Abstract

This article provides an overview of the uniform electron gas model (also known as jellium model) for electrons in solid matter. Historically, this model has provided the basis for the understanding of electron-electron interaction effects in metals and semiconductors and it currently plays a crucial role at the foundations of Density Functional Theory. We review the basic properties of the model, such as the existence of the Fermi surface, the exchange and correlation energy, static and dynamic screening, quasiparticles and plasmons and the possibility of electron crystallization and magnetic phases. The two-dimensional electron gas in systems such as quantum wells and graphene and in the presence of spin-orbit interactions and magnetic fields is also discussed.

Key points

- An electron gas pervades all known materials and is responsible for many of their observed properties
- Electrons in metals are described by Fermi liquid theory, whereby each electron behaves essentially like a free particle, dressed by interactions.
- The energy of the electron gas is controlled by the so-called “exchange-correlation” hole, arising in part from the Pauli exclusion principle, in part from the Coulomb interaction, whereby the average electrons density is reduced in the vicinity of an electron pinned at a given position.
- Electrons in metals rearrange around an external charged impurity in such a way that the impurity is “screened,” i.e., it becomes essentially invisible at large distance from the impurity. This screening effect is very effective in three dimensions, less so in lower dimension.
- The electron gas supports collective excitations of the charge density known as plasmons. Collective oscillation dominate the high-frequency response of the electron gas and give a large contribution to the correlation energy.
- Besides the liquid phases, other phases of the electron gas are possible, including crystalline and magnetic ones, and have been investigated by numerical Quantum Monte Carlo methods.
- The electron gas in two and one-dimensional structures may present non Fermi liquid behavior, such as the Luttinger liquid in one dimension and the quantum Hall liquid in two dimensions.

Notations and Acronyms

$\epsilon(q)$	Dielectric function
ϵ_F	Fermi energy
a_B	Bohr radius
B	Bulk modulus
e	Electron charge
$g(r)$	Pair distribution function
H	Magnetic field
h	Planck constant
$\hbar$	Planck constant h -crossed (h divided by 2π)
K	Compressibility
k_B	Boltzmann constant
k_F	Fermi wave number
ℓ	Magnetic length
m	Electron mass
m_c	Cyclotron mass
n	Electron density
p_F	Fermi momentum
q	Wave number
QMC	Quantum Monte Carlo
r	Distance
r_s	Dimensionless electron-electron coupling strength
S	Shear modulus
T	Temperature
α_{ee}	Electron-electron interaction coupling constant in graphene
λ	de Broglie wavelength
λ_{TF}	Thomas-Fermi screening length
ν_F	Density of states at the Fermi surface
$\chi(q)$	Density response function
$\chi_0(q)$	Static density susceptibility
χ_s	Spin susceptibility
ω_c	Cyclotron frequency
ω_P	Plasma frequency $v(q)$: Fourier transform of the Coulomb interaction

Introduction

The homogeneous gas of electrons (also known as jellium) is one of the most important basic models in the physics of condensed matter. It was introduced by Drude in 1900 to account for the electromagnetic properties of plasmas and was used by the pioneers of quantum mechanics in the early 1930s to model the sea of interacting valence electrons in a metal. The valence electrons are the outer electrons of an atom and determine how it interacts with its surroundings, but in a metal they are released by the atoms into a collective state. In the early studies, the ions of the crystalline lattice in the metal were smeared into a rigid uniform background of positive charge, which exactly balances the negative charge associated with the distribution of outer electrons. More generally, the background charge can be endowed with an ability to deform under pressure leading to a less widely known, but very useful “deformable jellium model.” Following the explosive growth of density-functional theory in the 1980s, the electron gas has become the basic reference system in most calculations of electronic structure not only for metallic or insulating solids and liquids, but also for atomic-scale systems and biomolecules.

In metals the density of valence (or conduction) electrons is high enough that many of their properties can be understood in terms of a picture in which they move almost independently of each other, forming a paramagnetic fluid made of equal numbers of up and down spins. The success of this counterintuitive single-electron picture of metals rests on the work carried out in the 1950s by Landau in developing the theory of Fermi liquids, as will be discussed in the next section. With decreasing density the potential energy associated with the Coulomb interactions between the electrons grows to dominate over their kinetic energy and ultimately at very low density the electron gas freezes into the “Wigner crystal,” in which the electrons become localized on lattice sites. This behavior is just the opposite of what happens with classical systems, where it is high density that favors a lattice structure. It has long been believed that crystallization of the electron gas in the jellium model is preceded, in an intermediate range of density, by the stabilization of a spin-polarized state in which the spins spontaneously align into a ferromagnetic state of order. This possibility was foreseen by Bloch in 1929 in the context of the Hartree-Fock approximation, and was initially confirmed by accurate calculations of the ground state energy based on quantum Monte Carlo (QMC) methods implemented on modern computers. The traditional

Fig. 1 The traditional QMC phase diagram for a three dimensional electron gas (Ceperley, 2004). Recent studies suggest that the narrow “polarized fluid” region is a computational artifact and does not exist in reality. Ceperley DM (2004) Introduction to quantum Monte Carlo methods applied to the electron gas. Proceedings of the International School of Physics Enrico Fermi, Course CLVII, edited by Giuliani GF and Vignale G. Amsterdam: IOS Press used with permission.

phase diagram of the electron gas in three dimensions is shown in Fig. 1 (Ceperley, 2004). However, more recent studies, also based on quantum Monte Carlo, have cast serious doubts on the existence of the ferromagnetic phase both in two-dimensions (Drummond and Needs, 2009) and in three dimensions (Holzmann and Moroni, 2020).

The electron gas framework, when widened to include artificial semiconductor heterostructures in which the electronic carriers are constrained to move in a plane (as in a quantum well) or on a line (as in a quantum wire) or under three-dimensional confinement (as in a quantum dot), provides much of the basic understanding that is necessary for modern condensed matter physics and nanotechnology. However, it is appropriate to note at this point that some more exotic properties of the valence-electron gas have come to the fore during the last few decades. These developments started with the idea of Cooper pairs in the BCS theory of superconductivity in metals and have been stimulated by discoveries of novel materials, such as the cuprate high- T_c superconductors and other oxides, or of novel physical effects such as the Kondo scattering against magnetic impurities and the fractional quantum Hall effect. The quantum theory of solids is now no longer confined to the electron as the quasiparticle of a Fermi liquid carrying an elementary charge and a spin, but in special situations the system of valence electrons reconstructs to produce quasiparticles that may behave like fragments of an electron, or more complicated objects such as composite fermions, composite bosons, holons and spinons. Also spin-orbit interaction effects, and linearly dispersing electrons in novel two-dimensional materials consisting of a single atomic layer (e.g., graphene) have been intensively studied. A complete discussion of electron gas theory up to 2005 can be found in the monograph by G. F. Giuliani and G. Vignale (Giuliani and Vignale, 2005). More recent topics will be briefly covered later in this article.

Ideal Fermi gas and Fermi liquid theory

Conduction electrons in normal metals under ordinary laboratory conditions form a highly degenerate Fermi fluid, in which the mean interparticle spacing a is a small fraction of the characteristic de Broglie wavelength $\lambda = h/p_{th}$ (here h is the Planck constant and p_{th} is the momentum of a particle of mass m having kinetic energy equal to the thermal energy $k_B T$, with k_B the Boltzmann constant and T the temperature). If for the moment one neglects all interactions, one can write the energy levels E of the gas in terms of the single-particle kinetic energies ε_k and of the number n_k of electrons in a single-particle state at energy ε_k : $E = \sum_k n_k \varepsilon_k$. Here k is a label specifying the momentum and the spin of each electron and $\varepsilon_k = \frac{\hbar^2 k^2}{2m}$ (with $\hbar = \frac{h}{2\pi}$) is the kinetic energy of each such electron. The Pauli exclusion principle restricts the values that n_k may take for particles of half-integer spin to $n_k = 0$ or 1 . A cell of volume h^3 in phase space can thus contain at most two electrons with opposite spins, so that in the ground state at $T = 0$ the electrons must have a spread of momenta in a range up to a maximum momentum p_F (the “Fermi momentum”). For N electrons with up and down spins inside a volume V and defining $k_F = p_F/\hbar$ (the Fermi wave number), one can write the density $n = N/V$ as $n = k_F^3/3\pi^2$ (The expression for the Fermi wave number becomes $(2\pi n)^{1/2}$ in two dimensions and $\pi n/2$ in one dimension, where n is given by N/A and N/L respectively). The Fermi wave number k_F is the radius of a spherical surface in wave number space

Fig. 2 Schematic representation of a section of the Fermi sphere for a paramagnetic electron gas, showing also a process of excitation of an electron-hole pair.

(the “Fermi surface”) and the energy of an electron at the Fermi surface is, by definition, the Fermi energy $\varepsilon_F = \hbar^2 k_F^2 / 2m$. This also is the lowest energy cost at which one may add a further electron to the gas (i.e., ε_F is the chemical potential of the gas at $T = 0$) and evidently increases with the electron density, since $k_F = (3\pi^2 n)^{1/3}$.

The notion of a spherical Fermi surface allows a vivid picture of ground state and excitations in a normal Fermi fluid. At $T = 0$, the single-particle states inside the Fermi sphere are fully occupied by the fermions and the states outside of it are empty. The momentum distribution (i.e., the occupation number of an electron state of given momentum and spin) thus takes a discontinuous change from 1 to 0 as the momentum crosses the Fermi surface. Thermal excitations at finite temperature bring fermions from states inside to states outside the Fermi surface, leaving “holes” behind and lowering the chemical potential of the gas (see the schematic picture in Fig. 2).

It is somewhat surprising that a number of properties of normal metals are observed to behave as predicted by the ideal Fermi-gas model, in spite of the electron-electron and electron-ion interactions that may be expected to lead to substantial departures from ideality. In particular, the electronic contribution to the specific heat of a metal increases linearly with temperature and the paramagnetic spin susceptibility is independent of temperature, both quantities being proportional to the density of electronic states at the Fermi surface, denoted by ν_F . These results are in agreement with the noninteracting electron gas model. The explanation of these behaviors was first given by Landau in what is now known as the “Landau theory of Fermi liquids.” Landau realized that at low temperature electrons with momenta close to the Fermi surface have limited opportunity to scatter against each other and thus change their state of motion. This is due to the combined constraints of energy conservation and the Pauli exclusion principle. These electrons therefore behave as if they were essentially free and their individual momentum is almost exactly conserved: such “almost free” particles are appropriately termed “quasiparticles.” Once one deals with quasiparticles rather than with “bare” electrons, the excitations of the fluid can be described as an almost ideal gas of quasiparticles. A crucial point in Landau’s theory is that the quasiparticles obey Fermi statistics, so that at low temperature the low-lying excitations of the interacting system are in one-to-one correspondence with those of the ideal noninteracting system, i.e., they are quasi-electron/quasi-hole pairs across the sharply defined Fermi surface. The correct behavior of the electronic specific heat and spin susceptibility follows at once.

There are, however, some major differences to be emphasized between quasiparticles and bare particles. First of all, a quasiparticle can be visualized as a bare particle “dressed” by a cloud of surrounding particles: the effect of this “dressing” is to rescale the relation between energy and momentum, introducing an effective mass m^* that depends on the strength of the electron-electron interaction. Thus, while the energy of a bare particle, relative to the chemical potential, is $\varepsilon_k - \mu \simeq \hbar k_F (k - k_F) / m$ for $k \simeq k_F$ (with m the bare mass of the electron), the energy of a quasiparticle is $\varepsilon_k^* - \mu \simeq \hbar k_F (k - k_F) / m^*$ where m^* is the effective mass. m^*/m is usually of order 1 in the electron gas at metallic densities, but it can rise into the hundreds for electrons in strongly correlated materials (heavy-fermion materials). Second, there are residual interactions between the quasiparticles, which cause the energy of a quasiparticle to change in proportion to the density of quasiparticle excitations already present in the system as a result of finite temperature and/or external excitation. These interactions are described by an (in principle, infinite) set of numbers known as “Landau parameters.” Third, the lifetime τ of a quasiparticle is not really infinite: its inverse goes to zero in the low-energy limit as $\hbar/\tau \propto (\varepsilon_k - \varepsilon_F)^2 / \varepsilon_F$ (for $T = 0$) or in the low-temperature limit as $\hbar/\tau \propto (k_B T)^2 / \varepsilon_F$ (for $\varepsilon_k = \varepsilon_F$). While this is much smaller than either $\varepsilon_k - \varepsilon_F$ or $k_B T$, justifying a posteriori the validity of the quasiparticle concept, it cannot be entirely neglected because it plays an important role in the calculation of the transport coefficients, when the system is driven out of equilibrium.

The effective mass of quasiparticles causes a shift in the density of states at the Fermi surface, $\nu_F^* / \nu_F = m^* / m$, which affects the values of the thermodynamic properties of the interacting electron gas relative to the ideal Fermi gas. For example, the low-temperature heat capacity of the interacting electron gas in three dimensions is given by $C_v = (\pi^2/3) k_B^2 T \nu_F^*$, which is still linear in T but is modified by a factor m^*/m relative to its noninteracting counterpart. Remarkably, the interaction between quasiparticles

(Landau parameters) does not enter this result. In contrast, the bulk modulus $n^2 d\mu/dn$ and the spin susceptibility (defined as the derivative of the spin magnetization with respect to an applied magnetic field) are affected both by the effective mass and by the quasiparticle interaction. In the electron gas these interactions reduce the bulk modulus and increase the spin susceptibility: the second effect can be seen as a consequence of interactions favoring the alignment of neighboring electron spins in a parallel configuration (see below). Theoretical calculations and experimental measurements of the effective mass and the quasiparticle interaction parameters in the electron gas are reviewed in Chapter 8 of Ref. (Giuliani and Vignale, 2005), to which we refer the reader.

Weakly interacting electron gas: Exchange effects

As a start to a calculation of the ground-state energy of the interacting electron gas, one might ask what is the distribution of electron pairs in the ideal Fermi gas as a function of their relative distance r . The pair distribution function, which is written in general as $g(r)$, is defined by computing the average number of electrons that lie within a spherical shell of radius r and thickness dr centered on any given electron and equating this to the quantity $ng(r)(4\pi r^2 dr)$. For the electron gas with equal numbers of up and down spins it can be written as $g(r) = [g_{\uparrow\uparrow}(r) + g_{\uparrow\downarrow}(r)]/2$, the average of the values for pairs of electrons with parallel spins and antiparallel spins. Whereas $g(r) = 1$ in a classical ideal gas, the probability of finding two electrons with the same spin at a distance r vanishes exactly as $r \rightarrow 0$. This property derives from the symmetry imposed by the Pauli exclusion principle, according to which the wave function of a Fermi fluid changes sign under the operation of exchange of two identical fermions. That is, the many-body wave function of the electron gas has a zero whenever two parallel-spin electrons overlap in space. The property $g_{\uparrow\uparrow}(0) = 0$ is an exact result and implies, by continuity, that each electron of given spin induces a local depletion of the density of electrons with the same spin in its surroundings. If we bear in mind that the Coulomb interactions between electrons are repulsive, it is seen that the presence of the “Pauli hole” that was introduced above is accompanied by a gain in potential energy of the electron gas. Exchange effects keep apart electrons with parallel spins and therefore reduce on average the Coulomb repulsion energy of parallel-spin pairs. In the ideal Fermi gas $g(r)$ is given by the expression

$$g_{\text{ideal}}(r) = 1 - \frac{9}{2} [j_1(k_F r)/(k_F r)]^2, \quad (1)$$

where $j_1(x) = (\sin x - x \cos x)/x^2$ is a spherical Bessel function. The shape of this function, which describes the Pauli hole in the ideal Fermi gas, is shown in Fig. 3.

Of course, no correlations exist at this level between pairs of electrons with antiparallel spins, therefore $g_{\uparrow\downarrow}(r) = 1$. The expression for $g_{\text{ideal}}(r)$ can be used to evaluate the ground-state energy in first-order perturbation theory. This calculation corresponds to the energy of the electron gas in the Hartree-Fock approximation, since by translational symmetry the self-consistent Hartree-Fock single-particle orbitals must be the plane-wave orbitals of the ideal gas. The result (in three dimensions) is

$$\begin{aligned} E_g^{\text{HF}}(r_s) &= \left(\frac{3}{5\alpha^2 r_s^2} - \frac{3}{2\pi\alpha r_s} \right) \text{Ryd} \\ &\simeq \left(\frac{2.21}{r_s^2} - \frac{0.916}{r_s} \right) \text{Ryd} \end{aligned}$$

per electron, with $\alpha = (9\pi/4)^{-1/3}$ and in units of the Rydberg ($1 \text{ Ryd} = e^2/(2a_B)$, with $a_B = \hbar^2/(me^2)$ being the Bohr radius). Here, we have introduced the crucial density parameter r_s by the definition $4\pi(r_s a_B)^3 = n^{-1}$, that is to say, r_s represents the mean distance between electrons in units of the Bohr radius. Electronic densities that are usually found in metals (metallic densities) have values of r_s ranging from $\simeq 2$ for Al to $\simeq 6$ for Cs. Much smaller as well as much higher values of r_s , corresponding to higher and lower densities respectively, can be found in semiconductors and semiconductor heterostructures.

Fig. 3 The Pauli hole surrounding an electron of given spin in the ideal Fermi gas in three, two, and one dimension.

The two terms in $E_g^{HF}(r_s)$ are the average kinetic energy and the average potential energy per electron, respectively, and their ratio is evidently proportional to $1/r_s$. This shows that the role of the electron-electron interactions becomes progressively more important as r_s increases, that is, as the density of the electron gas decreases. This counterintuitive fact, already noted in the Introduction, is now clearly seen to be a consequence of the Pauli exclusion principle which forces the electrons to occupy states of higher and higher momentum, and therefore higher kinetic energy, as their density increases. This is reflected in the behavior of the kinetic energy, which increases as $1/r_s^2$. The Coulomb interaction energy, on the other hand, scales as $1/r_s$, as expected from the $1/r$ behavior of the Coulomb potential, and therefore becomes negligible in comparison with the kinetic energy for $r_s \rightarrow 0$. Thus, the electron gas becomes effectively noninteracting in the limit of very high density.

Electron correlations: Calculation of the ground state energy

Naturally, the expression for the energy presented above (Eq. 2) is valid only when the effect of interactions is weak, i.e., in the high-density limit. Going beyond the Hartree-Fock expression requires the full machinery of many-body theory. This has been done in several steps, starting with the celebrated Random Phase Approximation (RPA) in the 1950s (Bohm and Pines, 1953; Gell-Mann and Brueckner, 1957) and continuing with semi-analytical theories such as the STLS theory (Singwi et al., 1968) (an extension of the RPA based on the Hubbard concept of “local field factor,” see below) and culminating with the essentially exact quantum Monte Carlo calculations by Ceperley et al. in 1980 (Ceperley and Alder, 1980). All these calculations take into account, with varying degrees of accuracy, the Coulomb correlations between electrons, i.e., the correlations that are caused by the Coulomb interaction in addition to the ones that are required by the Pauli principle.

It has been already remarked that no correlations between antiparallel spins are present in the ideal Fermi gas. This is no longer true in the presence of Coulomb interaction. The main effect is that the motions of opposite-spin electrons, which were completely uncorrelated in the ideal case, start to be correlated, and the depletion of the local electron density around each electron deepens since pairs of electrons with antiparallel spins are now kept apart by the Coulomb repulsion (The depletion of parallel-spin electrons is also somewhat deepened, but this is a relatively small effect since those electrons were already kept apart by the Pauli exclusion principle).

Fig. 4 shows the “Pauli-Coulomb hole,” calculated from QMC for increasing values of the coupling strength r_s (Ortiz and Ballone, 1994). An exact property of this function (also shared by the ideal pair correlation function of Eq. (1)) is that the total local depletion of electron density around the electron at the origin corresponds to taking away exactly one electron from its neighborhood. This ensures that the central electron plus the “exchange-correlation” (xc) hole surrounding it is an overall charge-neutral object. Within this constraint strong Coulomb interactions at low density cause a deepening of the xc hole and also a diminished contrast between parallel- and antiparallel-spin correlations (i.e., the Pauli exclusion principle becomes less important in the

Fig. 4 The Pauli-Coulomb hole in the interacting spin-unpolarized electron gas for various values of the coupling strength r_s : $r_s = 1$ (dotted line), $r_s = 3$ (dash-dotted line), $r_s = 5$ (dashed line), and $r_s = 10$ (full line). Adapted from Ref. Ortiz G and Ballone P (1994) *Physical Review B* 50: 1391.

presence of strong Coulomb repulsion). The diminished contrast between parallel and antiparallel spins plays a crucial role in keeping the electron gas paramagnetic, rather than ferromagnetic, at metallic densities.

Besides deepening the exchange-correlation (xc) hole, correlations also affect the kinetic energy of the electron gas by modifying the occupation numbers n_k of momentum states. In the ideal gas these occupation numbers are distributed according to a step function: $n_k = 1$ for $k < k_F$ and $n_k = 0$ for $k > k_F$. In the interacting electron gas the occupation numbers are reduced below 1 for $k > k_F$ and do not vanish for $k > k_F$ resulting in an increased kinetic energy (see Fig. 4). However a discontinuity in n_k persists at $k = k_F$, being a key signature of the existence of Landau quasiparticle. The discontinuity Z , known as quasiparticle renormalization constant, is loosely speaking, a measure of the fraction of the spectral weight of single-particle excitations that fall under the description of quasiparticles.

The calculation of the ground state energy of the electron gas requires both the pair correlation function and the momentum space occupation numbers. Alternatively, the energy can be calculated from the pair correlation function alone if the latter is known as a function of the coupling constant r_s' in the range $0 < r_s' < r_s$ (this is denoted by $g_{r_s'}(r)$). Then the formula for the total ground state energy is

$$\frac{E_g}{N} = \varepsilon_{kin}(r_s) + \frac{1}{r_s} \int_0^{r_s} dr_s' \int d\mathbf{r} \frac{e^2}{r} n [g_{r_s'}(r) - 1] \quad (2)$$

where $\varepsilon_{kin}(r_s) \simeq 2.21/r_s^2$ Ryd in 3D is the noninteracting energy per particle. In the early stages of the electron gas theory the pair correlation functions was obtained either perturbatively, or from approximate theories of the density response function which were developed to describe the phenomenon of *screening* (described in the next section). Modern approaches, like QMC, extract $g(r)$ directly from the many-body wave function. The results of these calculations have been cast in convenient parametrized form, which can be found, for example, in Chapter 1 of Ref. (Giuliani and Vignale, 2005) (Fig. 5).

Fig. 6 shows the energy per electron of the electron gas in 3D and 2D obtained from analytic fits to the QMC results. Qualitatively, its behavior is not very different from that of the Hartree-Fock approximation (Eq. 2), but of course it lies considerably below Hartree-Fock in the low density limit, going in 3D as $\simeq -1.8/r_s$ Ryd rather than $-0.916/r_s$ Ryd. Both energy curves shows a minimum, followed by and an inflection point (change in the sign of the curvature) at a slightly higher value of r_s . These two special points are marked by arrows in Fig. 6. The minimum indicates vanishing pressure P , and the inflection point is associated with a vanishing bulk modulus B .

One may wonder why negative values of P and B , occurring for values of r_s larger than the minimum and the inflection point respectively, are allowed at all. Normally, such negative values would indicate a thermodynamic instabilities of the system. The reason why these apparently unphysical values of P and B are allowed is that the jellium model includes a rigid background of positive charge. This rigid background fixes the density of the electron gas, which is therefore not allowed nor required to adjust its density to the minimum of the energy vs density curve. Likewise, the rigid background neutralizes any tendency of the electron gas to spontaneously contract or expand.

Fig. 7 shows the inverse bulk modulus $K = 1/B$ (also known as compressibility) and the spin susceptibility of the three-dimensional electron gas as calculated from QMC. Both quantities are plotted in units of their ideal-gas (i.e., noninteracting) counterparts. We also plot the same quantities obtained from the Hartree-Fock approximation. It is evident from these plots that while interactions generally enhance both the compressibility and the spin susceptibility, the specific effect of correlations (primarily correlations between antiparallel spin electrons) as revealed by the difference between Hartree-Fock and fully interacting results, is to further enhance the effect of exchange on the compressibility but at the same time to suppress the effect of exchange on the spin susceptibility. The second effect is the reason why ferromagnetism does not occur at metallic densities, and most likely at no density.

Fig. 5 Occupation numbers in momentum space for the three dimensional electron gas from Ref. (Senatore et al., 1996) for $r_s = 2$ (solid line) and $r_s = 5$ (dashed line). The occupation number discontinuity Z is shown.

Fig. 6 Energy vs r_s curves of a three- and two-dimensional electron gas. The arrows at the lower value of r_s indicate the points where the energy has a minimum (zero pressure), while the arrows at the higher values of r_s indicate the inflection points in the energy vs density relation (zero bulk modulus).

Fig. 7 Plot of the dimensionless compressibility K and spin susceptibility χ of a three-dimensional electron gas as a function of r_s . K_0 is the non-interacting compressibility and χ_P is the non-interacting spin susceptibility. In the Hartree-Fock approximation, which includes only exchange, both K and χ are enhanced relative to their non-interacting values. Correlations between opposite spin electron cause K to be even more enhanced, while χ is reduced.

Electron gas and density functional theory

The ground state energy of the uniform electron gas can be written as

$$E_g/N = \varepsilon_{kin}(n) + \varepsilon_{xc}(n), \quad (3)$$

where $\varepsilon_{kin} \simeq 2.21/r_s^2$ Ryd is the noninteracting energy per electron in 3D. The remainder $\varepsilon_{xc}(n)$ is known as the *exchange-correlation* (xc) energy (per particle): it includes the interaction contribution to the kinetic energy.

The xc energy has found widespread use in density functional theory. According to this theory, the effect of the electron-electron interaction on the ground state of an electronic system can be mimicked by a local exchange-correlation potential, $v_{xc}(r)$, which is added to the external potential and to the classical electrostatic potential of the charge distribution, so that interactions do not need to be taken into account explicitly. In the local density approximation the xc potential is given by

$$v_{xc}(r) = \frac{d}{dn} [n\varepsilon_{xc}(n)] \Big|_{n=n(r)} \quad (4)$$

i.e., it is the derivative of the uniform xc energy density with respect to density, evaluated at the local density of the system. Several parametrized expression of $\varepsilon_{xc}(r_s)$ (where r_s is a proxy for the density) are available in the literature (see Chapter 7 in Ref. (Giuliani and Vignale, 2005)).

Static screening

When a foreign charged particle (impurity) is inserted in the electron gas, the electrons respond by rearranging their density around the impurity in such a way that, at large distance from the impurity, the electric field created by the impurity is largely cancelled by the electric field created by the displaced electrons. This phenomenon is known as *screening*. To be more precise, let us denote by $V_{ext}(q)$ the Fourier transform of the potential created by the impurity. Then in the linear response approximation (valid at large distance from the impurity, where the potential is weak) the Fourier transform of the induced electronic density is

$$\delta n(q) = \chi(q)V_{ext}(q). \quad (5)$$

The static density response function $\chi(q)$ is a fundamental property of the electron gas. It allows us to calculate the net electric potential from the impurity and the displaced electrons as

$$\begin{aligned} V_{sc}(q) &= V_{ext}(q) + v(q)\delta n(q) \\ &= [1 + v(q)\chi(q)]V_{ext}(q) \\ &= \frac{V_{ext}(q)}{\varepsilon(q)} \end{aligned} \quad (6)$$

where $v(q)$ is the Fourier transform of the Coulomb interaction ($v(q) = 4\pi e^2/q^2$ in three dimensions), and $\varepsilon(q) \equiv [1 + v(q)\chi(q)]^{-1}$ is known as the *static dielectric function* of the electron gas.

The calculation of $\chi(q)$ and $\varepsilon(q)$ is a classic problems in electron gas theory. For the ideal noninteracting gas one has

$$\chi_0(q) = -v_F \left[\frac{1}{2} - \frac{q^2 - 4k_F^2}{8k_F} \ln \left| \frac{q - 2k_F}{q + 2k_F} \right| \right], \quad (7)$$

in three dimensions (similar analytical results are obtained in two and one dimension, see Fig. 8).

Here v_F is the density of states at the Fermi surface which for a three-dimensional ideal gas is given by $v_F = 3n/(2\varepsilon_F)$. For the interacting electron gas one has

$$\chi(q) = \frac{\chi_s(q)}{1 - v(q)\chi_s(q)}, \quad (8)$$

where $\chi_s(q)$, is known as the *proper* density response function and describes the response of the electronic density to the screened potential, i.e., $\delta n(q) = \chi_s(q)V_{sc}(q)$. The exact form of $\chi_s(q)$ is not known. The most popular approximation for $\chi_s(q)$ is the *random phase approximation*, which simply posits $\chi_s(q) = \chi_0(q)$. That is to say, the random phase approximation assumes that the electron gas responds as an ideal gas to the self-consistently screened potential. This leads to the widely used expression

$$\chi_{RPA}(q) = \frac{\chi_0(q)}{1 - v(q)\chi_0(q)}. \quad (9)$$

The corresponding dielectric function

$$\varepsilon_{RPA}(q) = 1 - v(q)\chi_0(q) \quad (10)$$

is easily seen to go to infinity as $1/q^2$ for $q \rightarrow 0$ (since $\chi_0(q) \rightarrow -v_F$ in this limit). This demonstrates the screening property described at the beginning of this section. The screened potential is suppressed by a diverging dielectric function in the limit of $q \rightarrow 0$, which physically corresponds to large distances from the impurity. Indeed, in this limit the RPA dielectric function reduces to $\varepsilon_{TF}(q) = 1 + (q\lambda_{TF})^{-2}$ where $\lambda_{TF} = (4\pi e^2 v_F)^{-1/2}$ is the Thomas-Fermi screening length. The Fourier transform of the screened potential $v(q)/\varepsilon_{TF}(q)$ is easily seen to decay exponentially as $e^{-r/\lambda_{TF}}$, where r is the distance from the impurity. However, this result is not quite accurate. A careful consideration of the logarithmic singularity of $\chi_0(q)$ at $q = 2k_F$ (see Eq. 7) reveals that the electronic density at a distance r from the impurity is asymptotically described by the expression

$$n(r) - n \propto \frac{\cos(2k_F r + \phi)}{r^3}. \quad (11)$$

Fig. 8 Static susceptibility of the Fermi gas in dimensions 1,2, and 3, as a function of wave number q , the vertical dashes show the position $q = 2k_F$.

The presence of the Fermi surface induces microscopic “Friedel oscillations” of wavelength π/k_F in the electron density. This result should be contrasted with the monotonic decay of the screened potential in a classical plasma, as found for instance in the Debye-Hückel theory of electrolytic solutions. Instead the effective potential created by an ion inserted in the electron gas, as well as the effective potential with which each electron interacts with the other electrons, are oscillating functions of distance showing both repulsive and attractive regions.

These results of the random phase approximation are essentially confirmed by more accurate many-body theories of the density response function. In these theories one often assumes that the electron gas responds as an ideal gas not to the self-consistently screened electrostatic potential, but to an effective self-consistent potential that is modified to take into account short-range exchange-correlation effects. In other words, one posits

$$\delta n(q) = \chi_0(q)[V_{\text{ext}}(q) + v(q)\delta n(q) - v(q)G(q)\delta n(q)] \quad (12)$$

where the second term in the brackets is the electrostatic potential created by the charge density distribution and the last term, containing the so-called local-field factor $G(q)$, generates the additional exchange-correlation potential (this is the term that is neglected in the RPA). Different many-body theories propose different approximate forms for $G(q)$, beginning with the first and perhaps most famous one, due to Hubbard, which goes as $G(q) \simeq (q^2/2)/(q^2 + k_F^2)$. In all cases $G(q)$ tends to zero as q^2 for $q \rightarrow 0$ reflecting the short-range nature of the xc effects. In these theories the density response takes the form

$$\chi(q) = \frac{\chi_0(q)}{1 - v(q)[1 - G(q)] \chi_0(q)}, \quad (13)$$

and the finite $q \rightarrow 0$ limit of $v(q)G(q)$ amounts to a many-body renormalization of the density of states at the Fermi surface, hence of the screening length.

Fast-forwarding over many years of theoretical development (the interested reader can find a review in Ref. [Giuliani and Vignale, 2005](#)). [Fig. 9](#) shows the plot of an analytical fit ([Corradini et al., 1998](#)) to the local field factor calculated directly from QMC by applying a periodic potential to electrons in the simulation box. More recent calculations and parametrization of $G(q)$ are also available ([Chen and Haule, 2019](#); [Ruzsinszky et al., 2020](#)).

The local field factor (also known in the literature through its alias, the exchange correlation kernel $f_{\text{xc}}(q) = -v(q)G(q)$), and its spin-dependent and frequency-dependent generalizations $G_{\sigma\sigma'}(q)$ and $G_{\sigma\sigma'}(q, \omega)$ respectively (where σ and σ' are spin indices), plays a crucial role in density functional theory and in many real-world applications of the electron gas model. In particular, the effective interaction between two electrons in the electron gas ([Kukkonen and Overhauser, 1979](#); [Kukkonen and Chen, 2021](#); [Dornheim et al., 2022](#)), which is constructed in terms of local field factors and differs from the effective interaction between two impurities embedded in the electron gas can be used to analyze the possibility of superconductivity in electronic systems ([Kukkonen and Chen, 2021](#)).

Dynamical screening and plasmons

While the low energy excitations of the electron gas are fermionic quasi-particles, the spectrum of long-wavelength density fluctuations is overwhelmingly dominated by high-frequency collective oscillations known as “plasmons.” The physical origin of plasmons is very simple. When the density of the electron gas is locally perturbed (say increased) electrons from neighboring regions move to screen the charge inhomogeneity, but in doing so they tend to overshoot the mark. Then they are pulled back toward the original disturbance and overshoot again, setting up an oscillation that decays slowly in time. The process is very similar to the one giving rise to sound waves in an ordinary gas, but there is an important difference: the restoring force responsible for the oscillation is the average long-range field created by all the electrons as opposed to, in the case of sound, the force arising from frequent

Fig. 9 Analytical fit to the local field factor calculated from QMC at $r_s = 2$ ([Corradini et al., 1998](#)). Notice that, unlike earlier approximations, this local field factor appears to grow indefinitely for large wave vector q .

short-range collisions between particles. Because of the long-range nature of the Coulomb interaction, the frequency of oscillations at wave vector q , denoted by $\omega_p(q)$, tends to be high and is given in the long-wavelength limit by

$$\omega_p(q \rightarrow 0) = \sqrt{nq^2 v(q)/m} = \sqrt{4\pi n e^2/m} \quad (14)$$

for the three-dimensional electron gas. The possibility of such oscillations was anticipated by Langmuir in 1928, long before the central importance of plasmons in the theory of the electron gas was recognized in the seminal work of Bohm and Pines in the 1950s. Notice that in Eq. (14) m is the bare electron mass in vacuum, *not* the quasiparticle effective mass. This simple long-wavelength result is exact, regardless of the relative strength of the electron-electron interaction, because a long-wavelength plasmon can be viewed as a rigid motion of the center of mass of the entire system, which does not involve the complex exchange and correlation effects that dress the motion of individual electron quasiparticles. Plasmon excitations are observed in inelastic scattering experiments on metals, using either a beam of fast electrons in electron energy loss spectroscopy or a beam of X-rays.

The simplest way to calculate the plasmon frequency is to look for the poles of the density response function, properly generalized to accommodate periodic potentials oscillating at a frequency ω , as a function of ω . This is easily understood by considering the definition of the dynamical density response function $\chi(q, \omega)$:

$$\delta n(q, \omega) = \chi(q, \omega) V_{ext}(q, \omega) \quad (15)$$

where $\delta n(q, \omega)$, $V_{ext}(q, \omega)$ are Fourier transforms of δn and V_{ext} in both space and time. The existence of a self-sustained plasma oscillation implies the possibility of a finite density fluctuation δn in the absence of an external field V_{ext} . This can only happen if $\chi(q, \omega)$ is infinite at the plasmon frequency. The general theory of the linear response guarantees that poles of $\chi(q, \omega)$ can only occur in the lower half of the complex frequency plane, but nothing prevents these poles from coming arbitrarily close to the real frequency axis. When this happens, the real part of the frequency is the plasmon frequency, while the imaginary part (small and negative) is related to the damping rate of the oscillation.

These general features are clearly brought out by the simplest approximation, the RPA, in which one has (with obvious generalization of Eq. (16))

$$\chi_{RPA}(q, \omega) = \frac{\chi_0(q, \omega)}{1 - v(q)\chi_0(q, \omega)}, \quad (16)$$

where $\chi_0(q, \omega)$ is the frequency-dependent response function of the ideal electron gas, which is known analytically and usually referred to as the *Lindhard function* (Giuliani and Vignale, 2005). The plasmon frequency is then obtained by the solution of the equation

$$1 - v(q)\chi_0(q, \omega) = 0, \quad (17)$$

which, in view of the exact result $\chi_0(q, \omega) \rightarrow nq^2/(m\omega^2)$ for $q \rightarrow 0$ and finite ω leads directly to Eq. (14). It is worth noting that the solution is purely real, i.e. the plasmon is not damped in the RPA. The situation is illustrated in Fig. 10A, where we see that plasmons

Fig. 10 (A) Plasmon dispersion in three and two dimensional electron gas (full lines) for $r_s = 2$. The dashed line represents the approximate two dimensional dispersion given by Eq. (17). Notice that both in three and two dimensions the long wavelength plasmons lie well above the edge of the particle hole continuum (shaded region), which protects them from decay into single electron-hole pairs. (B) Plasmon dispersion normalized to the plasmon frequency at $q = 0$. The symbols represent the experimental data for Na ($r_s = 3.93$, downward triangles), K ($r_s = 4.86$, upward triangles), Rb ($r_s = 5.20$, dots) and Cs ($r_s = 5.62$, squares). The solid lines give the theoretical plasmon dispersions obtained with the use of the STLS static local field factor.

oscillations being much higher in frequency than electron-hole pair excitations at the same wave vector, have no viable mechanism for decaying into single electron-hole pairs while obeying the conservation of momentum and energy. The situation changes, however, when one considers more sophisticated many-body theories beyond the RPA. In these theories the plasmon can decay by emitting *two* electron-hole pairs with large but nearly opposite momenta, so that the total energy and momentum match those of the plasmons. But even these more sophisticated theories predict plasmon damping to vanish as q^2 for $q \rightarrow 0$ in agreement with the general physical argument outlined above, namely the decoupling of the center of mass motion from the internal degrees of freedom of the electron gas (Kohn's theorem).

Fig. 10B shows the plasmon dispersion $\omega_p(q)$ for the three dimensional electron gas at various densities. These results are obtained using the STLS theory, which includes xc local field factors beyond the RPA. At high density (small r_s) the frequency increases with increasing q until a critical q is reached where the plasmon merges with the continuum of electron-hole excitations and is no longer a well-defined excitation. Here the RPA is qualitatively correct. But, as the density decreases, the plasmon dispersion flattens and even bends downward. This effect cannot be reproduced within the RPA and reflects the increasing importance of correlations at low density. A vanishing plasmon frequency at finite q would in principle indicate an instability of the uniform electron gas and the emergence of a highly correlated phase such as the Wigner crystal (see below).

Wigner crystallization

It has already been remarked that as the dimensionless electron spacing r_s increases (i.e., as the electron density decreases) the kinetic energy becomes less and less important relative to the potential energy associated with the Coulomb repulsions. In the 1930s Wigner had noticed that an optimal value is obtained for the potential energy of jellium if the electrons are placed on the sites of a body-centered cubic lattice structure. Localization of the electrons raises their kinetic energy and an electron crystal may become favored only at very low density, where the potential energy becomes dominant. Of course, in the crystal the electrons are not strictly localized on the lattice sites but execute vibrational motions around them. But the kinetic energy associated with this zero-point motion scales as $r_s^{-3/2}$ and becomes negligible compared to the interaction energy r_s^{-1} in the low density limit. At the same time, the amplitude of the zero-point oscillations scales as $r_s^{3/4}$ which is much smaller than r_s when r_s is large, justifying the picture of well-localized electrons in the limit under consideration. Of course, strong anharmonicity and high concentrations of lattice defects will be present in this quantum crystal near the transition density, or even at lower densities as the temperature is raised and the melting point is approached.

The problem of "Wigner crystallization" has become a classic in many-body physics, from both the theoretical and the experimental point of view. Quantum Monte Carlo studies have indicated that the ground state of three-dimensional (3D) jellium undergoes a first-order transition to a body-centered-cubic crystal around $r_s \simeq 100$, which is probably beyond the reach of experiments. In two dimensions, however, a first-order transition between the paramagnetic liquid and a triangular Wigner crystal is predicted to occur at a much lower value of $r_s \simeq 35$. The search for Wigner crystallization in the laboratory has therefore focused on quasi-2D assemblies of electronic carriers, mostly in artificial semiconductor heterostructures. The first unambiguous observation of Wigner crystallization was reported by Grimes and Adams in 1979 for electrons floating on top of a substrate of liquid ^4He in a quasi-classical regime. Metal-insulator transitions have subsequently been reported in quasi-2D systems of carriers subject to very strong magnetic fields in the fractional quantum Hall effect regime or in the presence of disorder and also in high-purity quasi-2D samples having exceptionally high carrier mobility. The observation of shear phonon modes, pinning-depinning transitions, and, more recently, geometric resonances occurring when the cyclotron radius of electrons becomes commensurate with the lattice constant, have been considered "smoking gun" evidence for Wigner crystallization.

Electron gas in reduced dimensionality

Electron gases in reduced dimensionalities present strong fundamental interest and high technological relevance. A general consequence of reducing the dimensionality is an increasing role of the electron-electron correlations at each given value of the dimensionless coupling strength r_s . This is ultimately a consequence of the modified topology of the electronic motions as the electrons are constrained to move in a plane or along a line or inside a quantum dot. This profoundly modifies the excitation spectrum of the ideal Fermi gas and often enhances the susceptibility to external perturbations.

Two-dimensional electron gases (2DEGs) are typically realized in semiconductor heterostructures at the interface between two different semiconductors. Typical examples are the inversion layer that forms at the surface of p -type Si in a metal-oxide-semiconductor (MOS) heterostructure with $M = \text{polycrystalline highly doped Si}$, $I = \text{SiO}_2$, $S = p\text{-type Si}$, and GaAs-AlGaAs-GaAs quantum wells, where the electrons reside in the AlGaAs region. These systems are two-dimensional in the sense that the motion of electrons in one direction (perpendicular to the heterostructure) is strongly quantized (i.e., all the electrons reside in the lowest quantized state of motion, which is separated from other states by a large energy gap) but the electrons move freely in the remaining two directions. What makes the systems particularly attractive is (i) the possibility of changing the electronic density by orders of magnitude by electrostatic gating (whereas the electron density in traditional metallic systems is essentially fixed by the ionic background) and (ii) the possibility of spatially separating the electrons from sources of disorder such as donor impurities, resulting in much higher mobilities. In recent years a new class of two-dimensional materials has emerged, which are based on single atomic

layers, such as a single layer of C atom (known as graphene) where the electronic density can be controlled by doping and by electrostatic gating. Within this family of systems many variations are possible, such as double electronic layers, multiple layers, and periodic superlattices. Recently, it has also become possible to twist two adjacent atomic layers relative to each other, thus generating incommensurate patterns known as moiré superlattices.

The Landau theory of Fermi liquids remains generally applicable to 2DEGs, in spite of some subtle differences. For example, the inverse lifetime of Landau quasiparticle in 2D varies as $(\epsilon_k - \epsilon_F)^2 \ln |\epsilon_k - \epsilon_F| / \epsilon_F$ as a function of energy and as $(k_B T)^2 \ln |k_B T / E_F| / E_F$ as a function of temperature. The logarithmic terms, which are absent in three dimensions, tend to decrease the lifetime of quasiparticles in 2D. 2DEGs are also much more sensitive to impurity scattering than their 3D counterparts. For example in the *non-interacting* 2DEG it is widely believed that all electronic states are localized in the presence of disorder. Electron-electron interactions restore the metallic state, but the inverse lifetime of quasiparticles now scales as $k_B T$, which is much larger than $k_B T^2 \ln T$, making these systems *marginal Fermi liquids*.

Static screening is greatly reduced in two dimensions as the electric field created by, say, an impurity can escape out of the plane and reach far away electrons in spite of the presence of compensating charge in the plane. Plasmon excitation are similarly reduced in frequency, their long-wavelength dispersion going as

$$\omega_p^{2D}(q \rightarrow 0) = (2\pi n e^2 q / m)^{1/2}, \quad (18)$$

which goes to zero for $q \rightarrow 0$ but still lies much above the energies of electron-hole pairs (linear in q). The above formula, incidentally, is exactly what one gets from Eq. (14), provided one takes care to use the correct form of the Fourier transform of the Coulomb potential in two dimensions, namely $v^{2D}(q) = 2\pi e^2 / q$. Thus, Eq. (14) is valid for the Galilean-invariant electron gas in any number of dimensions.

Similarly, the formula for the Friedel oscillations in the static screening density is modified due to the fact that the static density response function has a cusp at $q = 2k_F$ (see Fig. 6): this causes the amplitude of the oscillations to decay more slowly as a function of distance, v.i.z., as $1/r^2$ rather than as $1/r^3$.

Some of the most impressive examples of 2DEG physics have emerged in the presence of high magnetic field (quantum Hall effect) and in graphene where a peculiar band structure causes the free particle dispersion to be linear in k (mass less Dirac fermions). We will say more about these in the next two sections.

Consider now a system in which the conduction electrons are restricted to move along a line. The “Fermi surface” reduces to two points located at $k = \pm k_F$ and only forward or backward scattering processes are allowed at the “Fermi surface”. Here the Landau theory of Fermi liquid breaks down completely even in the absence of disorder. In fact, one can show that the Landau quasiparticles are no longer well-defined, as their inverse lifetime becomes comparable to or larger than their energy. Fermionic quasiparticles are superseded by linearly dispersing collective excitation (similar to plasmons) with bosonic character. This leads to a new paradigm of interacting electrons known as the “Luttinger liquid”. Characteristics of the Luttinger liquid are (i) There are no single-particle excitations: sharp peaks in the one-particle spectral function at $k = k_F$ are replaced by power-law singularities (ii) there is no Fermi surface: the discontinuity in the momentum distribution across the Fermi surface is replaced by a different type of nonanalytic behavior, (iii) Correlation functions between observables at different points in space decay with power laws with fractional exponents that depend on the strength of the interaction (iv) spin-charge separation occurs, i.e., spin-carrying collective excitations and charge-carrying collective excitations propagate with different velocities (in a normal Fermi liquid both spin and charge reside in the Landau quasiparticle and travel with the same velocity).

Even a simple look at the density response function of the noninteracting 1D Fermi gas shows how unusual this system can be. We have

$$\chi_0^{1D}(q) = -\frac{2m}{\pi \hbar^2 q} \ln \left| \frac{q + 2k_F}{q - 2k_F} \right|. \quad (19)$$

In Fig. 6 this density response function is plotted visa-vis its counterparts in 2 and 3 dimensions. In all cases there is a singularity at $|q| = 2k_F$, but the singularity gains strength as dimensionality is reduced, going from a logarithmic divergence in the derivative of $\chi_0(q)$ in 3D, to a discontinuity in the derivative of $\chi_0(q)$ in 2D, and finally to a logarithmic divergence in $\chi_0(q)$ itself in 1D. The divergence of the response means that the system is on the verge of an instability which will cause a massive reconstruction of the ground state as soon as additional interactions are turned on. For example, a monoatomic 1D conductor with a half-filled conduction band (one electron per atom) will gain electronic energy as soon as the electron-lattice coupling is turned on. The system undergoes a lattice distortion which opens a gap at the Fermi level through the formation of dimers. This is known as “Peierls instability”. Similarly, electron-electron interactions, even in the absence of electron-lattice coupling, lead to the formation of a Luttinger liquid.

Two-dimensional electron gas in graphene

In its pristine state graphene – a single layer of C atoms arranged in a honeycomb lattice – is a semimetal. Its valence and conduction bands touch at two points in the Brillouin zone (Dirac points) and the band dispersion is near these points with the two bands being mirror images of each other (see Fig. 11). This unusual form of the energy-momentum relation arises from the fact that the

Fig. 11 Band dispersion for massless Dirac fermions in the vicinity of the crossing point (Dirac point). In pristine graphene the Fermi level cuts the bands at the crossing point, so that there are no free carriers at zero temperature. Doping and/or electrostatic doping can shift the Fermi level away from the crossing point, as shown in this figure, creating a two-dimensional gas of massless Dirac electrons (case shown) or holes.

honeycomb lattice has two inequivalent sites in each unit cell, thus endowing the electron with an additional degree of freedom, formally equivalent to a spin, which has eigenvalues 1 or -1 depending on whether the electron is on or the other site. Under these conditions the electron wave function can no longer be described by a scalar plane wave: it becomes instead a two-component spinor, similar to the spinors that occur in the theory of massless relativistic Dirac fermions, but, of course, in a completely non-relativistic context. The pseudospin degree of freedom plays a crucial role in the calculation of the electronic properties of graphene. For a detailed review see Ref. (Castro Neto et al., 2009).

This system can host a 2DEG if we add electrons to the conduction band by doping or by electrostatic gating. Or it can host a two-dimensional hole gas if we remove electrons from the valence band. We will focus on the former case. Let us set the zero of the energy at one of the Dirac points, and let us also choose that point as the origin of momentum space. The main differences between this and the ordinary 2DEG stem from (i) the linearity of the conduction band dispersion $\epsilon_k = \hbar vk$ (notice the energy vanishing at the Dirac point $k = 0$) and (ii) the presence of occupied valence band states which are separated from empty conduction band states by energies of the order of the Fermi energy.

Concerning point (i) we notice that the linear dispersion breaks Galilean invariance, which mandates a quadratic relation between energy and momentum. On the contrary, this is the dispersion of massless relativistic particles (e.g., photons) which move with a preassigned speed v ($v =$ speed of light in the case of photons) independent of the momentum. For electrons in graphene, v is about $1/300$ the speed of light. As usual, we introduce the Fermi wave number k_F , which separates occupied from empty states within the conduction band (see Fig. 4): it is related to the two-dimensional electron density by $k_F = (\pi n)^{1/2}$, where we have taken into account not only the spin degeneracy but also the existence of two degenerate states associated with the same k in the vicinity of two different Dirac points. The Fermi energy is then $\epsilon_F = \hbar vk_F = \hbar v(\pi n)^{1/2}$.

An important difference between the 2DEG in graphene and the ordinary 2DEG emerges immediately from the above. Namely, the kinetic energy per particle $\sim \epsilon_F \propto \hbar v n^{1/2}$ and the potential energy per particle $e^2/r \propto e^2 n^{1/2}$ scale with the same power of density and the ratio of the second to the first is $\alpha_{ee} = e^2/(\hbar v) \sim 2$ in graphene. Thus, the electron gas in graphene does not seem to become “more ideal” as the density is increased, or “less ideal” as it is decreased – rather it presents us with an intermediate-coupling scenario at all densities (the actual value of α_{ee} is strongly affected by the dielectric environment of the graphene sheet, and can be larger or smaller than 2. The value quoted above is for a graphene sheet in vacuum). However, there is now another measure of the importance of interaction effects, and that is Λ/k_F where Λ is a cutoff wave vector, which determines the largest momentum of the occupied states for which the linear band model is still valid. The precise value of this cutoff wave vector is somewhat fuzzy, but is expected to be of order $1/a$, where a is the lattice constant. So even though α_{ee} is constant, interaction effects become stronger as k_F tends to zero, which is similar to the familiar situation, but leads to very different phenomenology in this case. For example it can be shown that the bulk modulus, proportional to $\partial\mu/\partial n$, is increased by interactions rather than decreased (Polini et al., 2007). This happens because when the electronic density is increased the Fermi level in the upper band moves farther away from the lower band: the negative exchange energy that is lost due to this effect outweighs the negative exchange energy that is gained by having more electrons in the upper band. The same phenomenon is observed for the spin susceptibility, which is now reduced, rather than enhanced, by interactions.

The existence of a finite k_F allows one to define an effective mass, even though the underlying particles are massless. To do this notice that in the ordinary electron gas the energy of a particle near the Fermi level can be approximated as $\epsilon_k - \epsilon_F = \hbar k_F(k - k_F)/m$, where m is the mass of the particles. Comparing this with the corresponding expression for massless fermions $\epsilon_k - \epsilon_F = \hbar v(k - k_F)$ one is led to the identification of an effective mass $m_c = \hbar k_F/v$, which is also known as the *cyclotron mass*. Thus, massless electrons in the vicinity of the Fermi surface behave like ordinary massive electrons with an effective mass $\hbar k_F/v$. This would seem a rather uninteresting story until we realize that this effective mass is density-dependent, because k_F is, and does indeed tend to zero in the limit of low carrier density.

These differences are duly reflected in the calculation of the ideal-gas linear response functions $\chi_0(q)$ and $\chi_0(q, \omega)$. For example in the ordinary 2DEG one has $\chi_0(q, \omega) \rightarrow nq^2/(m\omega^2)$ for $q \rightarrow 0$ and finite ω . For electrons in graphene this relation is replaced by $\chi_0(q, \omega) \rightarrow \epsilon_F q^2/(\pi\hbar^2\omega^2)$, which follows directly from the replacement of m by the cyclotron mass. Making use of this limiting form the plasmon dispersion for electrons in graphene is found to be

$$\omega_p(q \rightarrow 0) \simeq (2e^2\epsilon_F q)^{1/2}/\hbar, \quad (20)$$

which is qualitatively different from Eq. (18) because the coefficient of $q^{1/2}$ scales with density as $n^{1/4}$ rather than $n^{1/2}$. More importantly, the coefficient of $q^{1/2}$ is no longer “universal”, in the sense of being independent of the electron-electron interaction strength. In the Galilean-invariant electron gas, that universality stems from the fact that long-wavelength plasmons correspond to a rigid motion of the center of mass of the electron gas, and the center of mass is decoupled from the internal degrees of freedom. This is no longer the case for the electron gas in graphene. The center of mass motion does not decouple from internal degrees of freedom and the coefficient of $q^{1/2}$ in Eq. (18) (also known as *Drude weight*) is found to depend on the strength of the electron-electron interaction (i.e., the value of the coupling constant α_{ee}).

Additional differences between ordinary 2DEG and graphene 2DEG emerge when one consider the structure of the electron-hole excitation spectrum (see Fig. 12A), which now contains an entirely new branch in which electrons are promoted from a valence band state to a conduction band state with excitation energies comparable to the Fermi energy. Also plotted in Fig. 12B is the static density response function $\chi_0(q)$, which is distinctly different from the one plotted in Fig. 6, rising linearly, rather than decreasing, as a function of q , for $q > 2k_F$. The different form of the singularity at $q = 2k_F$ is reflected in a different form of the Friedel oscillations induced by an impurity. The amplitude of these oscillations decays as $\cos(2k_F r)/r^3$, at variance with the 2DEG result $\cos(2k_F r)/r^2$.

Coming to electron-electron interaction effects, we point out that, as the Fermi level approaches the crossing point with decreasing density, the Fermi liquid concept remains in force as long as $k_F > 0$, but the effective mass of quasi-particles is found to be logarithmically suppressed relative to the noninteracting cyclotron mass (Kotov et al., 2012). Another way of saying this is that the Fermi velocity v is renormalized to $v^*(k_F) > v$ where $v^*(k_F)$ diverges logarithmically in first order perturbation theory as $k_F \rightarrow 0$:

$$\frac{v^*(k_F)}{v} = 1 + \frac{\alpha_{ee}}{4} \ln\left(\frac{\Lambda}{k_F}\right). \quad (21)$$

While an increase of the velocity, leading to a reshaping of the bands near the Dirac point, has been experimentally observed, the divergence of $v^*(k_F)$ poses a problem of legitimacy for the microscopic perturbation theory on which this prediction is based. A non-perturbative approach is needed to analyze the $k_F \rightarrow 0$ limit. This approach is provided by the renormalization group, which is reviewed in Ref. (Kotov et al., 2012), and generally confirms the predictions of the weak coupling theory.

What is the effect of the interaction of the compressibility and the spin susceptibility of a the electron gas in graphene? In an ordinary 2DEG both are strongly enhanced by the interaction because the exchange energy becomes larger in absolute value (i.e., actually more negative) when the electron gas is spin polarized (spin susceptibility) or when the Fermi energy is pushed toward higher values. Surprisingly, the situation is reversed in the case of graphene 2DEG: detailed microscopic calculations (Polini et al., 2007) reveal that both the spin susceptibility and the compressibility are reduced by electron interaction. The explanation of this counterintuitive result lies in the fact that the exchange energy has a large contribution from the “spectator”

Fig. 12 (A) Schematic diagram of electron-hole pairs and collective excitations in graphene. Notice that the electron-hole pair excitation spectrum now contains transitions from the valence to the conduction band, as well as the usual transitions within the conduction band (B) The static density response function of the 2DEG in graphene. Notice the rapid linear increase as a function of q for $q > 2k_F$. This unusual behavior is a consequence of interband transitions which contribute to the polarizability of the electron gas in graphene.

electrons in the valence band. At first sight, it may seem that the distribution of electrons in the valence band should not be affected by the position of an electron in the conduction band for the same reason that the distribution of spin-down electrons is not affected by the presence of a spin-up electron in an ideal electron gas. But this is not true because valence and conduction band states of the same spin orientation (unlike states of opposite spin orientations) are not completely distinguishable at a given point in space: this gives rise to an inter-band exchange energy. When the chemical potential in the conduction band is raised, it turns out that the familiar gain in intra-band exchange is more than compensated by the loss of inter-band exchange (due to decreased overlap of the electron wave function at the Fermi level with valence band wave functions). Hence the sign of the effect is reversed.

Two-dimensional electron gas at high magnetic field

One of the most spectacular effects in the two-dimensional electron gas is the Quantum Hall Effect, which occurs when the gas is exposed to a strong perpendicular magnetic field H of the order of several Teslas and sufficiently low temperatures (von Klitzing et al., 1980; Tsui et al., 1982). The effect can be described as the quantization of the Hall conductance (i.e., the ratio I_H/V_L , where I_H is the transverse current and V_L is the longitudinal voltage) in multiples of the fundamental quantum of conductance $e^2/h \simeq 10^{-4}S$. Thus one has $I_H = \nu(e^2/h)V_L$ where ν is an integer in the integer quantum Hall effect or an odd-denominator fraction in the fractional quantum Hall effect. (The two versions of the effect, integral and fractional, have different physical origins, as we will see). The quantization is spectacularly accurate (one part in 10^{10}), in stark contrast with ordinary conductances, with or without magnetic fields, which depend strongly on the preparation of the sample, the level of purity, the temperature, and so on.

To explain this effect, we recall that the energy levels of an electron in 2D in the presence of a perpendicular magnetic field are the so-called Landau levels

$$\varepsilon_j = \left(j + \frac{1}{2}\right) \hbar \omega_c \quad (22)$$

where $\omega_c = eH/m$ is the cyclotron frequency and j is a nonnegative integer. These discrete levels replace the continuous distribution of energies $\varepsilon_k = \hbar^2 k^2 / (2m)$ of a free particle. However, since the number of states must be conserved, each of the Landau levels is macroscopically degenerate, i.e., for a particle confined to a 2D box of area A the number of degenerate states in each Landau level is

$$D = \frac{HA}{\Phi_0}, \quad (23)$$

where $\Phi_0 = h/e$ is the quantum of magnetic flux. Notice that this degeneracy is the same for all Landau levels, regardless of j .

We note in passing that the situation is qualitatively similar in graphene, except for the fact that the “mass” m is no longer a constant but scales with the square root of the electronic density. And since the electronic density, for a fixed number of occupied Landau levels, is proportional to H , as follows from the degeneracy of Landau levels, Eq. (23), it is quite plausible that the effective cyclotron frequency, which determines the energy of the Landau levels in Eq. (22) should become proportional to $\sqrt{H}$ rather than H . Indeed, the correct formula for the cyclotron frequency in graphene is v/ℓ , where $\ell = \hbar/(eH)$ is the magnetic length, related to the radius of a semiclassical orbit and described more precisely below.

The integer quantum Hall effect occurs whenever the Fermi level falls in the gap between two Landau levels, so that one has an integer number of fully occupied Landau levels. In a perfectly clean electron gas this situation would require an extremely accurate tuning of the electronic density, impossible to achieve in practice. Fortunately, the 2DEG in semiconductor heterostructures is sufficiently dirty to allow a significant density of localized electronic states to exist in the gap between Landau levels. These localized states do not contribute to the Hall effect, but play an essential role in allowing the Fermi level to remain inside the gap over a finite range of densities. According to conventional wisdom, this system should be an insulator, since all the states at the Fermi level are localized and unable to conduct electricity. Nevertheless, it is observed that the Hall conductance is ne^2/h where n is the number of occupied Landau levels. The apparent contradiction can be resolved in two ways.

The first approach is to recognize that the gap exists only in the bulk of the 2DEG. As the edges of the Hall bar are approached the Landau levels rise under the action of a confinement potential, and the n fully occupied ones eventually cross the Fermi level, thus closing the gap and generating conducting states on each edge. These “edge states” are like a one way street, allowing electrons to propagate only in one direction, with no possibility of backscattering. It is then shown that each pair of perfectly conducting edge channels (one state on each edge, with a potential difference between the two edges) contributes exactly a quantum of a conductance, e^2/h , so that the total conductance equals ne^2/h .

The second approach focuses on the bulk of the sample, which is now bent in the shape of an annulus (the so-called Corbino disk). In this description, one notices that the nominally insulating electron in the occupied Landau levels can still transport a current if they all move together in rough analogy with bags on a conveyor belt. The electromotive force is generated by a varying magnetic flux threading the annulus and is directed tangentially along the annulus. At the same time, the varying magnetic flux causes the centers of the electronic states in each Landau level to slowly drift in the radial direction, thus creating the Hall current. The precise quantization of the current follows from the fact that each additional flux quantum threaded through the annulus causes an integer number of electron to be transported from the inner to the outer edge.

The precise relation between the edge and bulk descriptions of the quantum Hall effect is still somewhat unsettled to date, particularly with regard to the spatial distribution of the Hall current. What is certain is that the effect has a topological origin, related to the existence of exactly n bundles of extended states (the Landau levels) below the Fermi level.

In contrast to the integral QHE, the fractional QHE occurs when the Fermi level falls in a gap created by electron-electron interactions within the lowest Landau level. The many-body origin of this gap has attracted tremendous attention from many-body theorists. A microscopic theory of the gap responsible for the $1/3$ effect was first proposed by Laughlin (Laughlin, 1983), who proposed that the state of the 2DEG in the $1/3$ quantum Hall state could be described by the elegant wave function

$$\psi(z_1, \dots, z_N) = \prod_{i < j}^N (z_i - z_j)^3 e^{-\sum_{i=1}^N |z_i|^2 / 4\ell^2} \quad (24)$$

where $z_i = x_i + iy_i$ is a complex variable that combines to the coordinates x_i and y_i of each electron, and $\ell = \hbar/(eH)$ is the magnetic length for magnetic field H (the magnetic length is the radius of a disk that encloses one quantum of magnetic flux). This is a highly correlated wave function in which the electrons avoid each other very efficiently (and thus keep their energy low) thanks to deep (third order) zeroes that occur when $z_i = z_j$. This wave function stands out because it associates three flux quanta to each particle. A similar wave function can be constructed with fifth, or seventh order zeroes, corresponding to $1/5$ and $1/7$ quantum Hall states, but not for even denominator states, since an even exponent would violate the required antisymmetry of the wave function under interchange of two particles. Starting from the state described by Eq. (24) any attempt to insert an extra electron in the system incurs a high energy cost (the gap) because this extra electron is not protected by the powerful zeroes of the ground state wave function and is therefore able to come closer to any of the pre-existing electrons. In addition, Laughlin showed that this extra electron would locally carry a fractional charge of $e/3$ – the remaining $2e/3$ being delocalized at the system's boundary.

Perhaps the simplest way to understand the physics of the Laughlin wave function is the *composite fermion theory* developed by Jainendra Jain (Jain, 1989). In this theory one assumes that each electron captures *two* magnetic flux quanta, thus forming what Jain calls a composite fermion. In the $1/3$ quantum Hall state each composite fermion sees an effective magnetic field arising from the remaining one flux quantum per electron that has not been used in the construction of the composite fermion. Thus the composite fermion in the $1/3$ quantum Hall state behaves like a regular electron in a completely filled Landau level. From this point of view, the fractional quantum Hall effect is nothing more than the integer quantum Hall effect of composite Fermions. This qualitative picture has been confirmed by many detailed calculations based on microscopic wave functions which were constructed starting from the composite fermion picture.

The collective excitations of the 2DEG at high magnetic field have also received a great deal of attention.

The most prominent excitation at $q = 0$, analogous to the plasmon, is the cyclotron resonance, corresponding to an excitation of the center of mass of the system, which rotates at the cyclotron frequency ω_c . Just as for the ordinary plasmon, the frequency of this motion is not affected by electron-electron interactions – a statement that goes under the name of Kohn's theorem.

Besides the center of mass mode, there are also intra-Landau level collective excitations, which have no analog at $H = 0$ and correspond to quadrupolar deformations of the wave function within the lowest Landau level. These excitations exhibit a many-body gap at $q = 0$ and have been observed in Raman scattering experiments.

Transport coefficients

The transport of charge, spin, energy and momentum in electronic systems is largely controlled by extrinsic agents such as impurities and lattice vibrations (phonons) and as such does not fall entirely within the realm of electron gas theory. But, if the system is extremely clean (no impurities) and the temperature is neither too high (so that phonons can be neglected) nor too low (to ensure frequent collisions between quasiparticles) then the intrinsic transport coefficients can be calculated entirely within electron gas theory. The intrinsic transport coefficients are (i) the spin diffusion constant D_s (proportional to the spin conductivity σ_s), which relates the spin current to the gradient of the spin density (ii) the thermal conductivity, κ , which relates the heat current to the gradient of the temperature, and (iii) the shear and bulk viscosities η and ζ respectively, which relate the traceless and traceful components of the momentum current (also known as stress tensor) to the corresponding components of the time derivative of the strain tensor. Notably, in a homogeneous electron gas there is no intrinsic transport coefficient for charge, i.e. no intrinsic electric conductivity or diffusion constant, since these quantities would be infinite by momentum conservation (one may say that the transport of charge in a perfectly clean electron gas proceeds by the emission of plasmons rather than by diffusion). The remaining three coefficients are finite even in the absence of impurity and phonon scattering because none of the three currents considered (the spin current, the heat current, and the momentum current) is conserved by the electron-electron interaction.

Quasiparticle collisions, which are responsible for the finite quasiparticle lifetime, are absolutely essential to calculate the intrinsic transport coefficient. In fact, these coefficients would all be infinite if collisions between the quasiparticles were completely neglected, which of course becomes a better and better approximation as the temperature is reduced. This counterintuitive result (divergence of the intrinsic transport coefficients for $T \rightarrow 0$) follows from the "asymptotic freedom" of the Landau quasiparticles in the low-temperature limit. Indeed, one can show that the transport coefficient are qualitatively described by the following formulas

$$D_s \sim v_F^2 \tau_s, \quad \eta \sim S \tau_\eta, \quad \zeta \sim B \tau_\zeta, \quad \kappa = n c_v v_F^2 \tau_q, \quad (25)$$

where S and B , are, respectively, the high-frequency shear modulus and the bulk modulus (both on the order of $n\varepsilon_F$) and c_v is the heat capacity (per particle) of the Fermi liquid. Here τ_s, τ_η etc. . . are transport relaxation times which are similar but not identical to the quasiparticle lifetime. All these scattering times diverge in the limit of zero temperature as $1/T^2$ in three dimensions. In two dimensions the situation is more complicated as the scattering times associated with spin diffusion and thermal conductivity diverge as $1/(T^2 \ln T)$, while the scattering time associated with the viscosity continues to diverge as $1/T^2$ (Hui-Hsing and Ebner, 1974). This is due to the fact that the scattering processes that are responsible for the $\ln T$ term are associated with zero momentum transfer and therefore do not contribute to the transfer of momentum in the liquid. Disregarding impurities and phonons, the divergence of the transport coefficients is cut off when the quasiparticle mean free path becomes comparable to the macroscopic size of the system, at which point the coefficients lose their hydrodynamic significance.

Explicit formulas for the calculation of transport coefficients were worked out in three dimensions in the works of Abrikosov and Khalatnikov (Abrikosov and Khalatnikov, 1959) and their formulas, originally developed for liquid ^3He , can be adapted to the electron gas. Similar formulas can be found in the literature for the Galilean-invariant 2DEG (Hui-Hsing and Ebner, 1974). For the 2DEG in graphene the transport coefficients were recently calculated in Refs. (Principi and Vignale, 2015; Principi et al., 2016)

Compensated semimetals, such as graphene itself at the charge neutrality point, offer the possibility of defining an intrinsic electric conductivity. This is because these systems contain equal numbers of electrons and holes, which drift in opposite directions under the action of the electric field. The relative motion of electrons and holes is hindered by electron-hole collisions, which tends to equalize the velocities of electrons and holes. This phenomenon is known as Coulomb drag and results in an intrinsic mechanism of resistance for compensated semimetals.

Spin-orbit interaction

We have until now neglected the possible coupling between the orbital motion and the spin of the electrons. This can be quite strong in three-dimensional heavy metals such Pt, and is responsible for important effects, such as the spin Hall effect and its inverse. If inversion symmetry is broken it is also possible to have an interesting phenomenon known as current-induced spin polarization, whereby a static spin polarization appears in response to an electric current. The inverse of this process, whereby an optically created spin polarization is converted to charge current, is known as “spin-galvanic effect” and has also been observed experimentally.

Starting in the first decade of the 2000 increasing attention has been paid to spin-orbit interaction effects in the 2DEG in semiconductor heterostructures and in graphene, with an eye to potential applications in the field of spintronics. In particular, several theoretical works have appeared, which combine the traditional jellium model with spin-orbit coupling.

Here we present the two most commonly used forms of spin-orbit coupling. The first, known as the Bychkov-Rashba interaction is most directly connected with the familiar spin-orbit interaction in atoms. It occurs in two-dimensional heterostructures in the presence of a perpendicular electric field E which breaks inversion symmetry along the z -axis. Its form is

$$H_{BR} = \alpha_{BR}(\mathbf{p} \times \hat{\mathbf{z}}) \cdot \boldsymbol{\sigma} \quad (26)$$

where $\mathbf{p}$ is the two-dimensional momentum σ is the Pali matrix representative of the spin, and α_{BR} is a velocity proportional to the magnitude of the electric field in the z direction.

The second form is known as the Dresselhaus spin-orbit coupling and its structure is quite different from that of an atomic spin-orbit coupling. This interaction arises from the projection of a three-dimensional band structure lacking inversion symmetry (for example the band structure of GaAs) over the two dimensions of a quantum well derived from the same material. Its form is

$$H_D = \alpha_D(p_x \sigma_x - p_y \sigma_y) \quad (27)$$

where again α_D has the dimensions of a velocity but now it does not arise from an external electric field but from the broken inversion symmetry of a three-dimensional solid.

A very interesting effect that arises from the Bychkov-Rashba and Dresselhaus spin-orbit interactions is known as “spin-momentum locking.” This simply means that, in the absence of electron-electron interactions, the orientation of the spin of an electron is uniquely determined by its momentum, being either parallel or antiparallel to the direction of an appropriate linear combination of the Bychkov-Rashba field $\alpha_{BR}(p_y - p_x)$ or the Dresselhaus field $\alpha_D(p_x - p_y)$, where (a, b) denotes a two-dimensional vector with components a along the x axis and b along the y axis. The two possible orientations of the spin have different energies and, if the spin-orbit coupling is sufficiently large, it is quite possible to have a situation in which electrons at the Fermi level are entirely locked in a single orientation, say parallel to the effective field, which however depends on the momentum $\mathbf{p}$ and therefore changes around the Fermi surface. The intriguing magnetic response properties of the resulting spin-textures in momentum space, as well as their effect on electronic transport are a rapidly evolving area of research.

Adding the Rashba-Bychkov and/or the Dresselhaus interactions to the conventional electron gas Hamiltonian creates an open field for theoretical investigations of the spin-orbit coupled electron gas. The Landau theory of Fermi liquid has been generalized to include spin-orbit coupling. Microscopic calculations of the correlation energy are lagging behind, mostly due to the numerical challenge of implementing accurate QMC calculations with spin-dependent wave functions. Such calculations will play an important role in the development of spin-density functional theory for system with strong spin-orbit interaction and non-collinear spins.

Conclusion

The electron gas is the universal glue that binds together all known materials. While the properties of materials vary dramatic from one realization to the other, the properties of the underlying electron gas are fairly universal and provide the basis for a universal treatment of Coulomb interaction effect in materials as demonstrated by the widespread use of Density Functional Theory in materials science. In addition, the electron gas theory underlies the modern technology of semiconductor-based electronic devices. The study of novel phase of the electron gas, assisted by spin-orbit interaction, magnetic fields, and low dimensionality, is an extremely active field of fundamental research in which new discoveries are being made at a fast pace.

Abstract

In a brief review, the definitions and the main features of the four so-called Jahn-Teller effects (JTEs) in atomic matter are illustrated by the cross sections of their adiabatic potential energy surfaces (APES). They characterize the four specific cases of electronic structures of polyatomic systems that lead to spontaneous symmetry breaking, termed as proper JTE, *pseudo*-JTE (PJTE), *hidden*-JTE, and *hidden*-PJTE, respectively. The latter two of them, the “*hidden*” versions, are also appended with examples of electronic structure calculations for clarity. Then follows the warning that APES are not direct observables: although they serve well for some important qualitative predictions of possible (virtual) properties, further considerations may be necessary to reveal them. A recently developed experimental method of investigation of local JTEs in solids by means of ultrasonic measurements is described. The novel properties of matter induced by the underlying JTEs are inexhaustible; several examples of more recent achievements in this field are presented exploring the role of the JTEs in local properties (e.g., in qubits), and cooperative effects in crystals, including the PJTE origin of ferroelectricity, multiferroicity, and orientational polarization of perovskite crystals. A novel trend of manipulating polyatomic properties via influencing their JTEs parameters is developing, applied so far to changing crystal sublattices by specific doping, and planarization of two-dimensional systems by coordination to external groups.

Key points

- The Jahn-Teller effects (JTEs) describe the fundamental property of atomic matter to undergo spontaneous symmetry breaking (SSB), and the conditions of its occurrence.
- There are (presently known) four modifications of the JTEs: the proper JTE, pseudo-JTE, and more recently revealed *hidden*-JTE and *hidden*-PJTE. Examples of the hidden versions are shown.
- The induced by these SSB observable properties of polyatomic systems are vast, but their widespread attribution to just the form of the adiabatic potential energy surface (APES) may be inadequate (or even misleading), as the APES are not directly observable properties.
- Latest achievements in this field, especially in relevance to condensed matter, include revealing the APES of local centers in crystals with JTEs by means ultrasonic investigations, magnetic field induced tunneling between orthogonal JTE formations in solids, the role of the JTEs in the properties of qubits, demonstrated using the SiV(0) center in diamond as an example.
- A series of effects due to cooperative JTEs in crystals, including ferroelectricity, multiferroicity, and orientational polarization leading to giant flexoelectricity and permittivity, shows the way of continuous further developments in this field.
- The knowledge of the origin of SSB in polyatomic systems as due to the JTEs is used to work out procedures for manipulating their properties by external influence targeting the underlying JTEs parameters. Examples include modification of crystal sublattices and planarization of two-dimensional systems.

Introduction

The series of four Jahn-Teller effects (JTEs), formulated below, emerges from the fundamental property of polyatomic systems to undergo spontaneous symmetry breaking (SSB), subject to electronic degeneracy and pseudodegeneracy. It was formulated first in 1934 by L. Landau in a discussion with Teller (1972), by stating that *the configuration of nonlinear polyatomic systems in electronic degenerate states undergoes spontaneous distortion that removes the degeneracy*, later proved and published by Jahn and Teller (1937). Since the first formulation, this background idea underwent tremendous evolution, directly influencing the theory of molecular and solid state structures and their properties (see, e. g., Bersuker, 1966; Englman, 1972; Köppel et al., 1984; Bersuker and Polinger, 1989; Chancey and O'Brien, 1997; Bersuker, 2006, 2021, and references therein). First, it was shown that the spontaneous distortion may take place also when the degenerate energy level is slightly split (pseudodegenerate) (Öpik and Pryce, 1957). This, at first sight not very significant enlargement of the JTE subjects, later on served as a trigger for a similar, but much more important conclusion that sufficiently strong vibronic coupling between any two electronic states (often ground and excited) with any energy gap between them, under certain conditions leads to instability and distortion of the polyatomic configuration. This is the pseudo JTE (PJTE) (Bersuker, 1966, 2006, 2013a,b, 2021). More recently, the Landau idea of SSB was extended to polyatomic structures with neither degeneracy, nor pseudodegeneracy in the ground state of their high-symmetry configuration, but with strong JTE or PJTE in their low-lying excited state, which penetrate the ground state producing global distorted configurations; these SSB were termed as *hidden-JTE (h-JTE)* and *hidden-PJTE (h-PJTE)*, respectively (Bersuker, 2009, 2020a).

With the PJTE, *h*-JTE and *h*-PJTE added to the original JTE, we conclude that there are no configurations of polyatomic systems that can a priori be excluded from the possibility of SSB. Moreover, it was proved that the JTE and the PJTE are the only source of instability and spontaneous distortions of high-symmetry configurations of polyatomic systems (see Bersuker et al., 1984; Bersuker and Polinger, 1989; Bersuker, 2006, and references therein). And, more general, degeneracy and pseudodegeneracy are the only source of SSB in the whole spectrum of transformations in matter from elementary particles to nuclei, to atoms, molecules and solids (Bersuker, 2016).

In what follows in this brief review of the subject, we introduce the JTEs in a general, mostly qualitative view, with more recent examples of their influence on observable local and cooperative properties in solids. In so doing, we try to avoid the mathematical deductions of the underlying nonadiabaticity and vibronic coupling effects, which can be easily find in the reference literature.

Four modification of the JTEs. Adiabatic potentials vs observables

The definitions of the four modifications of the JTEs are illustrated in Fig. 1. They all are consequences of the vibronic coupling interactions in the ground or low-lying excited states, and are given here in terms of the cross-sections of the adiabatic potential

Fig. 1 Illustration to the definition of the four types of electronic configurations causing the four kinds of Jahn-Teller effects; for simplicity, in all four cases only one symmetrized coordinate Q of the low-symmetry nuclear displacements from the reference high-symmetry configuration at $Q = 0$ is shown; E_{JT} and E_{PJT} are the JTE stabilization energies, and Δ denotes energy gaps. (a) In the case of *proper JTE* the system is unstable, it has no minimum of the APES at the point of electronic degeneracy $Q = 0$, but it may be stable in the distorted configurations at $\pm Q_0$; (b) The *pseudo-JTE (PJTE)* case: there is no degeneracy at $Q = 0$, but the system is unstable due to the pseudodegeneracy when $\Delta < F^2/K_0$ (see the text); (c) *Hidden-JTE*: there is neither degeneracy nor pseudodegeneracy in the ground state of the system, but there is a relatively low-lying excited state that has a JTE, which is so strong, $E_{JT} > \Delta$, that it penetrates the high-symmetry ground state, producing a global minimum with a distorted configuration; (d) *Hidden-PJTE*: the same situation as in the *hidden-JTE*, but the intervening excited state has a strong PJTE with $E_{PJT} > \Delta_0$, instead of the JTE.

energy surfaces (APES), showing only one distortion coordinate of the system. In all the four cases the APES has no global minimum in the high-symmetry configuration, meaning possible SSB, as in the original Landau formulation for the JTE.

This simplified, one-dimensional presentation of the four JTEs is for visual demonstration only, allowing one to get a glimpse on the rich variety of the specific vibronic coupling effects in polyatomic systems, which lead to SSB. We see that while the JTE, nominally, takes place in all the cases of electronic degeneracy, the other three cases are rather limited by the energy gaps and the vibronic coupling strength between the involved electronic states. In particular, the condition of pseudodegeneracy leading to the PJTE is as follows:

$$\Delta < F^2/K_0 \quad (1)$$

where 2Δ is the energy gap between the coupled electronic states, F is the vibronic coupling constant, and K_0 is primary force constant (the stiffness of the systems with respect to the Q displacements). The analytical conditions for the h -JTE ($E_{JT} > \Delta$) and h -PJTE ($E_{PT} > \Delta_0$), graphically seen in Fig. 1, are slightly more complicated (Bersuker, 2009, 2020a). In reality, the APES and the consequent effects are multidimensional with many ramifications and particular cases, including (most important) strong dependence on external perturbations.

The picture as a whole for the JTE and PJTE, their modifications and applications, are well presented in books and reviews, cited in the Introduction (see, e.g., Bersuker, 2006, 2021 and references therein). The present brief account of the subject is just to review the latest achievements in the evolution of understanding of these effects and their general applications, allowing the reader to find the necessary details and proofs (most important, mathematical proofs and deduction of these effects based on first principles) in the cited literature. The hidden modifications, h -JTE and h -PJTE, are relatively new, much less studied, and so far not widely applied to relevant local properties in solids. Therefore, we bring here some examples that further illustrate their physical meaning.

For illustration of the h -JTE, consider the ozone molecule O_3 , which is unstable in its high-symmetry D_{3h} configuration. Its full APES has three equivalent minima, in each of which the regular triangular configuration is distorted to an obtuse triangle. The distortion could not be explained, neither by the JTE, as its ground state in the high-symmetry configuration is nondegenerate, nor by the PJTE, because of the very high energy of the relevant excited state, which does not follow the condition of pseudodegeneracy (1). Fig. 2 illustrates the results of ab initio calculations of the energy profiles of the O_3 APES in the cross-section along one of the coordinates of the e type displacements from the high-symmetry configuration, in the ground and the lowest excited state (Garcia-Fernandez et al., 2006). It shows convincingly that the instability of the high-symmetry configuration in the ground state is due to the very strong JTE in its excited E state, which penetrates the ground state to produce the three distorted configuration of the JTE in the $E \otimes e$ problem, exactly following the above definition of the h -JTE (Fig. 1c).

As for the h -PJTE, a series of demonstrative examples emerged from a class of molecular systems and local centers in crystals with electronic configurations e^2 and t^3 half-occupied by 2 and 3 electrons with parallel spins, respectively (half-filled closed shells), which take place, for example, in systems with at least one threefold (or higher) symmetry axis (Garcia-Fernandez and Bersuker, 2011). For instance, the CuF_3 molecule (and any similar local formation in crystals) falls in this category. The electronic configuration of the Cu^{3+} ion in this molecule (or cluster) is $(t_{2g})^6 e^2$, occupied by 8 electrons, two in the e^2 configuration. Its

Fig. 2 Cross-section of the APES of the ozone molecule along the Q_0 component of the double degenerate e mode (one of the three equivalent distortions in the $E \otimes e$ problem of the JTE), obtained by numerical ab initio calculations including the highly excited E state (at $\Delta \sim 9$ eV), explicitly demonstrating that the ground state distorted configurations are due to the JTE in the excited state. The global minimum is at $Q_0 = 0.69$ Å and the E - A avoided crossing takes place at $Q_0 \sim 0.35$ Å. Reprinted from Bersuker I.B. calculated energy level scheme is shown in Fig. 3. We see that the ground state of the undistorted regular triangular configuration of this system is a spin triplet, 3A_2 , but a strong PJTE mixing of two excited singlet states, 1A_1 , and 1E , produces an additional lower-energy state with a distorted configuration. The latter becomes the global minimum of the APES when the stabilization energy E_{PJT} is larger than the energy gap Δ to the ground state. This example is of special interest also because it leads to an interesting molecular magnetic-dielectric dualism (García-Fernández and Bersuker, 2011; Bersuker, 2020b). Indeed, the distorted configuration has a non-zero dipole moment, but a zero magnetic moment (zero spin), whereas the undistorted configuration has no dipole moment, but a nonzero magnetic moment of the spin-triplet electronic state.

As mentioned above, the h -PJTE may take place in any system with half-filled e^2 or t^3 electronic configurations. Fig. 4 shows the general scheme of the energy level states of systems with e^2 configurations (similar schemes are available for t^3 systems). The CO_3 molecule may serve as an example of h -JTE combined with h -PJTE (Liu et al., 2009).

An important feature of the JTEs is that they are defined in a general way by the specifics of their APES. However, APES are not directly observable properties of the system. Ignoring this circumstance played as a difficulty in finding the first experimental confirmation of the original JTE, and continues to be an impediment in correctly understanding of what observable changes in the properties of polyatomic systems, caused by these effects, are expected. The situation is aggravated by its being continuously ignored in many books, reviews, academic lecturing, and even in some scientific publication, leading to erroneous conclusions in prediction of observable properties, induced by the JTEs.

Nevertheless, serving as the potential energy in the Schrödinger equation for observables, the specific APES features of the JTEs may allow for qualitative predictions of some of the expected properties. First, we note that for any given high-symmetry configuration, there are several (or an infinite number of) equivalent low-symmetry distortions that satisfy the JTE requirement of SSB. This means that the APES should be an equivalent-multiminimum surface, or a trough of continuing minima. In other words, the JTEs, in general, predict a multiminimum potential with a complicated picture of nuclear dynamics and observables that depends of the form of this potential. However, again, the multiminimum potentials of the APES, by themselves, are not directly observable experimentally.

The consequences for observable properties of the system induced by its JTEs are inexhaustible, they are considered in many books, reviews, and original publications. In general, without additional consideration, they cannot be reduced to observable distortion of space configuration of free polyatomic systems, as it is stated in “primitive” definitions in some literature on the JTEs. More important, the form of the APES is sometimes erroneously taken as the direct observable property of the system. For instance, in some recent publications devoted to the influence of spin-orbital coupling (SOC) on the JTE, the authors calculated the changes of the APES by SOC perturbation, assuming that this is the observable effect. Excluding the possibility of exact solution, the correct approximate calculations would get first the energy levels and wave functions with the APES of the JTE system, and then include the SOC as a perturbation (if it is sufficiently small), which would yield the vibronic reduction of the SOC (Ham, 1972).

It follows that, strictly speaking, we cannot define the observable properties of the system with JTEs just based on their APES, without further investigation. The direct way to do this is to solve the relevant Schrödinger equation including the nuclear dynamics. In overcoming the difficulties in solving the problem with arbitrary APES of JTEs, we explore, as usual, approximations and limiting cases (see in: Englman, 1972; Bersuker and Polinger, 1989; Bersuker, 2006; Köppel et al., 1912, etc.). In condensed matter problems, the most important way to reveal the observable properties in the JTEs is to involve external perturbations (see below).

JTEs in local properties of solids. Examples

As mentioned above, exploration of the observable JTEs in molecular systems and condensed matter is presently well developed and continuing, presented in a series of books, reviews, and original papers, cited in the Introduction (for more citations, see Bersuker, 1984; Perlin and Wagner, 1984; Bersuker, 2021). As it is clearly seen from the definitions in section “Four modification of the JTEs. Adiabatic potentials vs observables,” all JTEs are of local origin, grounded in the specifics of the local interactions between electronic states and nuclear displacements (vibronic coupling); they define the local properties of solids directly. Note that in the overwhelming majority of cases, point defects (local impurity, dopant, and vacancy centers), as well as the bulk local centers in crystals, have degenerate or pseudodegenerate electronic ground and/or excited states (both explicit and hidden), subject to the JTEs, which influence all their properties. Below are several examples of the latest achievements in this field. Obviously, in condensed matter, the local JTEs distortions may interact strongly, resulting in cooperative effects, discussed in the next section.

With regard to JTEs, local properties in solids (inherent to neutral molecules, ions, clusters, impurity and vacancy centers in solids, qubits, quantum dots, thin films, etc.) are studied by a variety of spectroscopies, including optical, electron spin resonance (ESR), X-ray, EXAFS, and other related methods, and also with the same methods under influence of external fields and pressure. Cooperative interactions in crystals with JTEs lead to structural, magnetic, ferroelectric, multiferroic, etc., phase transitions. The study of the JTEs shows also how we can manipulate condensed matter properties by employing external perturbations that directly influence the underlying JTEs parameters. Below we show examples from the latest achievements on these topics.

Ultrasonic exploration

Recently developed studies based on measurements of ultrasonic attenuation and velocity change induced by JTEs impurities in crystals (Gudkov and Bersuker, 2012; Averkiev et al., 2017a,b; Gudkov et al., 2020), demonstrated high efficiency in obtaining important information about the structure and properties of the system. Distinguished from ESR, optical, and other similar experimental methods, in which the measurement perturbation engages primarily with the electronic subsystem, ultrasound interacts directly with the nuclear arrangement, thus determining the main features of the APES of the JTEs centers. When propagating through the crystal containing the latter, and dependent on direction of propagation and polarization, the ultrasonic wave unequally shifts the minima of the multiminimum APES, making them nonequivalent, thus creating a non-equilibrium distribution of the JT complexes over their energy levels (Fig. 5). This non-equilibrium state relaxes to equilibrium during a characteristic relaxation time τ . The relaxation process introduces an additional channel of energy loss, which results in the ultrasonic wave attenuation, velocity change, and dispersion (Gudkov and Bersuker, 2012; Averkiev et al., 2017a).

It follows that in relation to ultrasonic experiments the subsystem of JT centers in crystals is very special: due to their well-defined local multiminimum APES and strong anisotropy with respect to the polarized ultrasound wave, it produces specific anomalies in the ultrasound propagation that are absent in other ultrasound absorbers (the latter thus can be easily excluded). Ultrasonic experiments with doped crystals directly reveal the symmetry properties and the local APES parameters, including the JT active modes (trigonal, tetragonal, and orthorhombic JTE distortions, respectively), linear and quadratic vibronic coupling constants, extrema point positions on the APES, including minima positions and energy barriers between them. In other words, ultrasonic investigations provide for a unique possibility to reveal the whole APES of JTE centers in crystals and consequent properties. Below we show an example that illustrates this statement.

The dopant Cr^{2+} center in a fluorite crystal, $\text{SrF}_2\cdot\text{Cr}$, is subject to the JTE problem $T \otimes (e + t_2)$, which (with the quadratic vibronic coupling terms included) yields the predicted by the theory six-dimensional APES in the space of two tetragonal and three trigonal symmetrized atomic displacements around the Cr^{2+} center (Bersuker and Polinger, 1989; Bersuker, 2006). It includes six equivalent orthorhombic global minima with four trigonal and three tetragonal saddle-points between them. This most complicated APES of a JTE system was fully reconstructed experimentally based on ultrasonic measurements, thus demonstrating their unique possibilities (Averkiev et al., 2017a). The temperature-dependent relaxation attenuation of the longitudinal ultrasonic waves (propagating along

Fig. 5 Distortions of the APES of a JTE center in crystals (subject to the $E \otimes e$ problem), produced by the ε_4 -type ultrasonic mode deformations, which violate the equivalency of the minima and the equilibrium conditions within the JT subsystem. Panels (a), (b), (c) show the APES distortions in accordance with the wave's profile shown in panel (d) (U_z is the instant displacement of the atoms perpendicular to the propagation direction z axis at $t = t_0$). the [110] axis of this crystal), induced by the JTE distortions, is shown in Fig. 6. It allows extracting the relaxation time τ as a function of temperature (Fig. 7) using well-established relations (Averkiev et al., 2017a).

The relaxation attenuation of the shear ultrasonic wave is directly determined by the linear vibronic coupling constants in tetragonal F_E and trigonal F_T distortions: $|F_T| = 3.66 \cdot 10^{-5}$ dyn and $|F_E| = 0.63 \cdot 10^{-5}$ dyn (Averkiev, 2017a). On the other hand, the temperature dependence of the relaxation time in Fig. 7 shows that there are two barriers of relaxation. At low temperatures, first the lower barrier between the tetragonal distortions ($V_0 = 45.6 \text{ cm}^{-1}$) is overcome, followed by the barrier between the larger trigonal distortions ($V_0 = 271 \text{ cm}^{-1}$) at higher temperatures. The two barrier heights give us also the energy positions of the tetragonal and trigonal saddle-points, respectively. Involving the more complicated part of the JTE theory for a T term with the quadratic terms of the vibronic coupling included (Bersuker and Polinger, 1989) and some additional considerations about the elastic properties and local low-frequency vibrations of this crystal, the authors revealed also the stabilization energy of the orthorhombic minima

Fig. 7 Temperature dependence of the relaxation time obtained from the attenuation of the c_{44} normal mode at the frequency of $\omega = 105$ MHz. The square symbol corresponds to the condition $\omega\tau = 1$. The lines represent two exponential functions $\tau = \tau_0^{(j)} \exp(V_0^{(j)}/kT)$ overcoming tetragonal (Curve 1, $\tau_0^{(1)} = 5 \times 10^{-11}$ s, $V_0^{(1)} = 390$ K = 271 cm $^{-1}$) and trigonal (curve 2, $\tau_0^{(2)} = 0.5 \times 10^{-8}$ s, $V_0^{(2)} = 65$ K = 45.2 cm $^{-1}$) potential barriers. Reproduced from Averkiev N.S., Bersuker I.B., Gudkov V., Zhevstovskikh I.V., Sarychev M.N., Zherlitsyn S., Yasin S., Shakurov G.S., Ulanov V.A., Surikov V.T. (2017a) Manifestation of the Jahn-Teller effect in elastic moduli of strontium fluorite crystals doped with chromium ions. *Journal of Physics Conference Series* 833: 012003. Copyright 2017 IOP publishing.

$E_{JT}^{or} = 562$ cm $^{-1}$, the quadratic vibronic coupling constant $W_{E,T} = -2.1 \times 10^{-4}$ dyn/cm, the primary force constants K_{OE} and K_{OT} , and the symmetrized coordinates of the tetragonal, trigonal, and orthorhombic extrema points of the six-dimensional APES, as well as the splitting of the lowest vibrational states in the minima produced by the tunneling between the six equivalent orthorhombic minima, $\Gamma \sim 19$ cm $^{-1}$. Thus the first full description of a rather complicated APES created by the JTE in a crystal center was obtained experimentally by means of ultrasonic investigation (Averkiev, 2017a).

Another example of ultrasound investigation of JTEs in local properties of crystals illustrates its efficiency in combination with *magnetic field influence* (Averkiev et al., 2017b), which is important in view of possible applications in electronics and spintronics. It was shown that in some JTE systems, an external magnetic field induces tunneling transitions between local configurations in polyatomic systems with orthogonal electronic states, for which no tunneling is expected, the tunneling levels being produced by the magnetic field. In a variety of impurity and vacancy centers in cubic crystals and similar molecular systems with cubic and icosahedral symmetry in different aggregate states (including thin films and quantum dots) the ground or excited electronic state may be threefold degenerate T state, subject to the $T \otimes e$ problem of the JTE. In these cases (ignoring the SOC reduced by the vibronic coupling), the APES has three equivalent minima along the three tetragonal distortions, in which, distinguished from the $E \otimes e$ problem, the three electronic functions of the three distorted configurations in the minima are orthogonal, so no tunneling or direct relaxation transitions between them are allowed. This is one of the JTE problems where tunneling between the equivalent minima in the ground state is forbidden.

It was shown that an external magnetic field removes this prohibition, producing a new channel of tunneling and direct relaxation transitions between the distorted orthogonal configurations (Averkiev, 2017b). The theory of the JTE $T \otimes e$ problem in magnetic fields, and in interaction with ultrasound, and the ultrasonic experimental observations of the novel effect were carried out using the Cr^{2+} impurities in the crystal $\text{ZnSe}:\text{Cr}^{2+}$ as a typical example. In this impurity center the ground state is electronically threefold degenerate with three orbital wave functions of a hole in the closed-shell $3d^5$ configuration, transforming as vectors. They can be described by an orbital momentum operator with $L = 1$, hence being subjects to magnetic field influence. Experimental data show that the JTE distortions in the impurity center under consideration are tetragonal, thus evidencing for the $T \otimes e$ problem.

Tunneling effects in JTE systems, in general, were predicted in 1961–1962 (Bersuker, 1961, 1962) and observed in optical, ESR, and ultrasonic experiments in a variety of systems with non-orthogonal minima states. In ultrasonic experiments tunneling manifests itself in the temperature dependence of relaxation time τ_{rel} , where, by lowering the temperature, the function $\tau_{\text{rel}}(1/T)$ changes from $\tau_{\text{rel}} \approx (v_0)^{-1} \exp(V_0/k_B T)$ in the activation mechanism with over-the-barrier transitions to the tunneling mechanism with vanishing temperature dependence. The analysis of the temperature dependence of the relaxation time in zero magnetic field shows the absence of tunneling in the JT system of Cr^{2+} centers in the ZnSe crystal. When a weak magnetic field is applied to the system at low temperatures, a sharp increase in the attenuation of ultrasound is observed, illustrated in Fig. 8 (Averkiev, 2017b).

A microscopic theory was developed showing that the magnetic field produces a new relaxation channel associated with tunneling between the orthogonal distorted configurations, made possible due to magnetic-induced coupling between their (otherwise orthogonal) orbital states (Averkiev, 2017b). The rather cumbersome deductions carried out for the ultrasound attenuation in magnetic fields in $\text{ZnSe}:\text{Cr}^{2+}$ can be concluded as follows. In zero magnetic field there is a relaxation attenuation of ultrasound driven by the relaxation time, which is determined by one-phonon processes in the absence of tunneling between

Fig. 8 Magnetic field dependence of ultrasound attenuation $\Delta\alpha = \alpha(B) - \alpha(0)$ at different temperatures, for the ultrasound frequency $\omega/2\pi = 33$ MHz and magnetic field induction $B||[110]$. Inset: the peak of attenuation in magnetic fields at $T = 1.3$ K at the same frequency, but different directions of B : curve 1, $B||[110]$; curve 2, $B||[001]$. Reproduced with permission from ref. Averkiev N.S., Bersuker I.B., Gudkov V.V., Zhevstovskikh I.V., Baryshnikov K.A., Sarychev M.N., Zherlitsyn S., Yasin S., Korostelin Yu.V. (2017b) Magnetic field induced tunneling and relaxation between orthogonal configurations in solids and molecular systems. *Physical Review B* 96: 094431. Copyright 2017 American Physical Society.

equivalent JTE configurations. In weak magnetic fields up to 0.1 T (up to 3 mT for $B||[001]$) the ultrasonic attenuation is still determined by the relaxation mechanism, but due to magnetic field induced tunneling there is a sharp increase in relaxation rate, which leads to a sharp increase of attenuation. Finally in magnetic fields above 0.1 T there is a transition to a quasi-resonance mechanism of attenuation with a smooth decrease of attenuation up to the fields of 2 T (Averkiev, 2017b).

Qubits for spintronics in quantum information devices

Investigations are continuously developing in application of the JTE and PJTE theory to revealing the structure and properties of specific defect centers in diamond and similar crystals (impurity, dopant and vacancy centers and their combinations), which are promising candidates as quantum bits (qubits) for a wide variety of quantum technologies, including quantum sensors to repeater nodes for long-range quantum networks. The studied qubit centers include a large variety of neutral atoms as impurities plus a vacancy, denoted as $XV0$ ($X = N, Si, Ge, Sn, Pb$, etc.), or a charged atom plus vacancy (e.g., NV^-), as well as many other combinations.

As could be expected, all of these artificial defects in diamond, potential qubits for spintronics, are strongly affected by the JTE, and many of them are also influenced by the PJTE (the possibility of the hidden JTEs was not explored as yet). The JTEs essentially alter the energy level positions and their ordering, including the spin-orbit splitting, as well as optical transitions between them with intersystem crossing and zero-phonon lines, making electronic structure calculations without the JTEs absolutely unreliable. For instance, one of the most important features of such qubits, the presence of an excited spin state with a sufficiently long lifetime, strongly depends on the spin-orbit coupling (SOC). As mentioned above, the dynamic JTE may reduce the SOC by orders of magnitude (Ham, 1972). With regard to qubits, this was confirmed by direct calculations in exploring the active electronic 3E state of the NV^- center in diamond: the calculation of the SOC without the JTE yields it equal to 15.8 GHz, which is about three times larger than the measured one (Thiering and Gali, 2017). The idea was further developed by more accurate calculations of the JTE and SOC simultaneously (non-perturbatively) for a series of qubit centers in diamond, $GeV0$, $SnV0$ and $PbV0$, which show that the JTE reduces the SOC by an order of magnitude (Ciccarino et al., 2020). These fine structure details reveal the new physics of color center qubits in diamond, and present a pathway to identify them experimentally.

To show the JTE implication in these problems in somewhat more technical detail, we bring here a brief demonstration of the JTE in the $XV0$ ($X = Si, Ge, Sn, Pb$) centers in diamond with numerical results for $SiV0$ (Thiering and Gali, 2019). The JTE in these centers is produced by multi-electron states, in which the JTE stabilization energy E_{JT} is larger than (or of the same order of magnitude of) the interelectron repulsion that leads to the multiplet term formation. In such cases it is more convenient to consider first the vibronic coupling in the separate one-electron molecular-orbital (MO) states, and then their interelectron interaction. This leads to the product-JTE (see in: Bersuker, 2006); in the case under consideration, it yields (in the excited state) two orbital degenerate MOs, e_g and e_u , coupled via E_g displacements, denoted as the $(e_g \otimes e_u) \otimes E_g$ product-JTE, which, upon interelectron interaction, results in two triplet terms, $^3\tilde{A}_{2u}$ and $^3\tilde{E}_u$. Fig. 9 illustrates the results of the calculations performed for the $SiV0$ center in diamond (Thiering and Gali, 2019).

Similar in trend (but different in detail) APES with ground and excited energy levels and transitions between them, showing the defining role of the JTE or PJTE (or both), were found in all the other candidates for qubits in quantum information systems, that were explored theoretically; there are no known defects in diamond and other similar systems with no JTE or PJTE implications.

Fig. 9 (a) Adiabatic potential energy surface of the SiV(0) center in diamond that shows the $(e_g \otimes e_u) \otimes E_g$ product JTE in the excited state. The separate JTE in the two MOs, e_g and e_u , produce two “Mexican hat”-type surfaces with stabilization energies $E_{JT}^{(1)}$ and $E_{JT}^{(2)}$; (b) Their resulting electronic triplet terms $^3\tilde{A}_{2u}$ and $^3\tilde{E}_u$, respectively, with an energy gap of 6.7 meV. The vertical absorption, luminescence, and zero-phonon lines are shown by blue, red, and black arrows, respectively; (c) geometry of the undistorted SiV(0) center with D_{3d} symmetry, showing also the carbon-localized X and Y coordinates of the JTE active normal mode E_g (Bersuker, 2006). Cooperative properties in crystals. Ferroelectricity, multiferroicity, and orientational polarization

As mentioned above, cooperative interactions between crystal centers with JTEs lead to important observable properties. The first investigations of cooperative JTE were performed on rare-earths orthovanadates and similar systems (Ghering and Ghering, 1975; for more details, see Bersuker and Polinger, 1989; Polinger, 2009; Kaplan and Vekhter, 1995), showing their rich influence on solid state properties, leading to structural phase transitions. Before that, the cooperative PJTE as leading to ferroelectricity was suggested (Bersuker, 1966), its full theory being developed in more recent times. We bring here an outlook of its latest achievements (Bersuker, 2017a, 2018; Bersuker and Polinger, 2020; Polinger and Bersuker, 2018).

Cooperative PJTE, ferroelectricity

Actually, the explanation of the origin of ferroelectricity in perovskite type crystals (like BaTiO_3) as triggered by the local PJTE was the first application of this effect to solving a major solid state problem (Bersuker, 1966). It was shown that in the centrosymmetric configuration of the perovskite crystals, local dipolar distortions in the metal centers may occur due to the PJTE. Without the latter, the existing theories implied that the spontaneous polarization of such crystals is due to a self-consistent cooperative mechanism, in which the local (repulsive) dipolar displacements are compensated by their long-range dipole-dipole attractions. However, all the experimental data, accumulated in years, show unambiguously that the instant local dipolar distortions are there in all the phases of the crystal, including the paraelectric phase, before the phase transition to the ferroelectric one (see, e.g., Ravel et al., 1998; Stern, 2004). The PJTE theory solves this problem (Bersuker, 1966, 2018, 2019; Bersuker and Polinger, 2020).

Fig. 10 shows the local electronic structure of the octahedral $[\text{TiO}_6]^{8-}$ cluster in the paraelectric phase of BaTiO_3 . Very briefly, the local PJTE emerges from the vibronic mixing of the ground state A_{1g} , formed by the fully populated highest occupied (HO) six molecular orbitals (HOMO) t_{1u} and t_{2u} (mostly oxygen 2p orbitals), with three lowest unoccupied MO (LUMO) t_{2g} (mostly titanium 3d orbitals), a total of 9 MO's, by the polar t_{1u} type normal coordinates Q_x , Q_y , and Q_z . This PJTE $(A_{1g} + T_{1u}) \otimes t_{1u}$ problem results in a 9×9 secular equation. Its solution yields the following APES of the TiO_6^{8-} cluster, obtained already in the first paper on the subject (Bersuker, 1966, 2018):

Fig. 10 The energy-level correlation diagram (not to scale) for the octahedral cluster $[\text{TiO}_6]$. HOMO t_{1u} and t_{2u} (of mostly oxygen origin) and LUMO t_{2g} (mostly titanium) are one-electron energy levels of the orbitals that are coupled in the PJTE. The shown electron populations correspond to the particular case of $[\text{TiO}_6]^{6-}$. Reprinted from Bersuker I.B. (2006) *The Jahn-Teller Effect*. Cambridge, UK: Cambridge University Press. Copyright 2006 I. B. Bersuker.

$$U(Q) = \frac{1}{2}K_0Q^2 - 2 \left[\sqrt{\Delta^2 + 2F^2(Q^2 - Q_x^2)} + \sqrt{\Delta^2 + 2F^2(Q^2 - Q_y^2)} + \sqrt{\Delta^2 + 2F^2(Q^2 - Q_z^2)} \right] \quad (2)$$

where $Q^2 = Q_x^2 + Q_y^2 + Q_z^2$, 2Δ is the energy gap between the mixing electronic states, K_0 is the primary force constant for the Q displacements (stiffness of the crystal without the vibronic coupling), and F is the vibronic coupling constant (H is the Hamiltonian),

$$F = \left\langle 2p_z(\text{O}) \left| \left(\frac{\partial H}{\partial Q_x} \right) \right| 3d_{xz}(\text{Ti}) \right\rangle \quad (3)$$

In a more rigorous treatment by the Green's functions approach (Polinger et al., 2015), the local PJTE in the cluster unit was appended with the bulk crystal properties by taking into account the interaction of the Ti ion with the whole crystal via its electronic and vibrational bands. It improved the results by yielding appropriately band-averaged parameters instead of the local cluster ones.

The three-dimensional APES (2) has a specific form. Under the condition.

$$\Delta < 8F^2/K_0 \quad (4)$$

the surface (2) has a maximum (meaning instability) when the Ti ion is in the center of the octahedron, eight equivalent minima placed along the four trigonal axes, in which the Ti ion is displaced toward three oxygen ions (away from the other three); higher-in-energy 12 equivalent saddle points along the six C_{2v} axes, at which the Ti ion is displaced toward two oxygen ions (at the top of the lowest barrier between two near-neighbor minima); and next six higher-in-energy equivalent saddle points, at which the Ti ion is displaced to one of the oxygen ions along the fourfold axes (Bersuker, 1966, 2018).

With additional two experimentally determined structural constants, the band-averaged energy gap $2\Delta = 2.8$ eV and the vibrational frequency at the bottom of the trigonal minimum $\hbar\omega_E = 193$ cm^{-1} , all the main parameters of this APES, shown in Table 1, were estimated, including K_0 , F , the positions of the minima $Q_x = Q_y = Q_z = Q_0$ and first saddle points $Q_x = Q_y = q_0$, $Q_z = 0$, their PJTE stabilization energies, and the tunneling splitting Γ . The latter is a characteristic measure of the energy barrier between the near-neighbor minima of the APES.

The four phases of BaTiO_3 emerge directly from this APES by gradually populating the states in the minima with temperature and stepwise overcoming its barriers (Bersuker, 1966; Polinger, 2013; Polinger et al., 2015). Of particular interest is also the prediction of disorder in the orthorhombic and tetragonal ferroelectric phases and in the cubic paraelectric phase. As mentioned above, it was confirmed later together with a variety of other predictions of the theory that have no explanation in displacive theories (see in: Bersuker, 2018). Using the numerical estimates of Table 1, the interaction between the PJTE induced local dipole moments in BaTiO_3 was taken into account in a mean-field approximation, in which both the local off-center displacement and the mean field of the environment are interdependent in a self-consistent way (Polinger, 2013). It yields the experimentally observed phase transitions in BaTiO_3 with reasonable values of Curie temperatures.

Table 1 Numerical values of the PJTE vibronic coupling and APES parameters of the Ti active centers in the BaTiO_3 crystal (Polinger et al., 2015).

K_0	2Δ	F	$\hbar\omega_E$	Q_0	q_0	$E_{JT}[111]$	$E_{JT}[110]$	Γ
55 eV/Å ²	2.8 eV	3.42 eV/Å	193 cm^{-1}	0.14 Å	0.16 Å	−1250 cm^{-1}	−1130 cm^{-1}	35 cm^{-1}

Multiferroicity

The PJTE theory was extended to formulate the necessary condition of coexisting magnetic and ferroelectric (multiferroicity) properties in ABO_3 perovskite crystals with B as a transition metal ion in a d^n configuration, $n = 1, 2, \dots, 10$ (Bersuker, 2012, 2013b), that found already confirmation in experiments (Domracheva et al., 2013; Raymond et al., 2014; Weston et al., 2016) and ab initio calculations. Multiferroicity implies that the ferroelectric crystal, which is a dielectric, has also a nonzero magnetic moment, meaning unpaired electrons. In the ferroelectric BaTiO_3 with perovskite ABO_3 structure the d^0 configuration of the Ti^{4+} ion has no unpaired electrons, and attempts to obtain ferroelectricity in perovskites with d^n , $n > 0$, configurations of the transition metals B ions were unsuccessful for a long time (Barone and Picozzi, 2015). The PJTE origin of ferroelectricity not only explains how the possible ferroelectric properties of perovskite crystal may coexist with unpaired electrons, but it shows also when this coexistence may take place. Moreover, for d^n ions with $n = 3, 4, 5, 6$, and 7 , which are directly influenced by the well-known transition metal high-spin/low-spin crossover, one may expect the coexistence of three phenomena: ferroelectricity (FE), magnetism (M), and spin crossover (SCO). This, in turn, leads to a quite novel phenomenon: magnetic-ferroelectric (multiferroics) crossover (MFCO), creating a rich variety of possible magnetoelectric and related effects (Bersuker, 2012, 2013b). The vibronic (PJTE) theory, exclusively, reveals the role of spin in spontaneous polarization of crystals.

The above MO energy scheme for an octahedral cluster BO_6^{8-} in Fig. 10 shows the MO electron population of the d^0 transition metal ion, e.g., when $\text{B} \equiv \text{Ti}$, with the HOMO electron configuration $(t_{1u})^6 = (t_{1u}\downarrow)^3(t_{1u}\uparrow)^3$, where the arrows up and down indicate the two spin states. The energy term of this configuration is $^1A_{1g}$. The excited state with opposite parity is formed by the one-electron, $(t_{1u}\uparrow) \rightarrow (t_{2g}\uparrow)$ or $(t_{1u}\downarrow) \rightarrow (e_g\uparrow)$, excitation, resulting in the lowest excited ungerade term $^1T_{1u}$ at the energy gap 2Δ . In this case, the PJTE at the B center, under the condition of instability $\Delta < 8F^2/K_0$ (Eq. 4), produces a polar displacements of the B atom along $[111]$ -type directions, which triggers the ferroelectric polarization (see section “Cooperative PJTE, ferroelectricity”).

For the d^1 configuration of the B ion instead of the d^0 , the HOMO becomes $(t_{1u}\downarrow)^3(t_{1u}\uparrow)^3(t_{2g}\uparrow)^1$ with the term $^2T_{2g}$, and the LUMO, taking into account Hund's rule, is $(t_{1u}\downarrow)^2(t_{1u}\uparrow)^3(t_{2g}\uparrow)^2$ with the lowest excited ungerade term $^4T_{1u}$. Hence the two closest terms of different parity, *possess different spin multiplicity*, and hence *they do not mix by the vibronic coupling*; the latter does not contain spin operators. In principle, there may be higher in energy electronic configurations of opposite parity with the same spin as the ground state one, but they are at much larger energy gaps Δ , and therefore less appropriate to satisfy the condition of instability (4) (numerical estimates show that the condition (4) may be very restricting). A similar picture emerges for d^2 configurations for which the two lowest terms of opposite parity are $^2T_{2g}$ and $^5T_{1u}$.

The situation changes for d^3 . Indeed, in this case the HOMO is $(t_{1u}\downarrow)^3(t_{1u}\uparrow)^3(t_{2g}\uparrow)^3$ with the ground state term $^4A_{1g}$, and in the low-spin conditions of the strong ligand fields (large t_{2g} - e_g separation in Fig. 10), the LUMO is $(t_{1u}\downarrow)^2(t_{1u}\uparrow)^3(t_{2g}\uparrow)^3(t_{2g}\downarrow)^1$ with the lowest ungerade term $^4T_{1u}$. Therefore, for d^3 configurations (e.g., Mn^{4+}) in sufficiently strong ligand fields the situation becomes again favorable for the PJTE and polar distortions, but in this case, distinguished from the d^0 case, the system possess also a magnetic moment created by three unpaired electrons. However, if the ligand field is weak and the separation t_{2g} - e_g is small, the high-spin arrangement of the excited electronic configuration takes place, and the excitation electron occupies the $e_g\uparrow$ orbital instead of $t_{2g}\downarrow$; the LUMO configuration under Hund's rule becomes $(t_{1u}\downarrow)^2(t_{1u}\uparrow)^3(t_{2g}\uparrow)^3(e_g\uparrow)^1$ with the lowest ungerade state $^6T_{1u}$. Here again there is no PJTE on dipolar distortions and no ferroelectric instability. This is one of the examples, which shows explicitly how the spin states interfere directly into the possible local polar displacement and ferroelectricity.

In this way all the d^n configurations with $n = 0, 1, 2, \dots, 10$, were explored (Bersuker, 2012) showing that in perovskite ABO_3 crystals, only B ions with configurations d^0 , d^3 -low-spin, d^4 -low-spin, d^5 -low-spin and high-spin, d^6 -high-spin and intermediate-spin, d^7 -high-spin, d^8 , and d^9 can, in principle, produce multiferroics, provided the criterion of instability (4) is satisfied. If the (in general, hardly significant) contribution of higher excited states can be ignored, transition metal ions B with configurations d^1 , d^2 , d^3 -high-spin d^4 -high-spin, d^6 -low-spin, d^7 -low-spin, and d^{10} are not expected to produce multiferroics under this mechanism of proper ferroelectricity. Experimentally observed multiferroics with such B ions, for example, $\text{Mn}^{4+}(d^3)$, $\text{Cr}^{3+}(d^3)$, $\text{Mn}^{3+}(d^4)$, $\text{Fe}^{3+}(d^5)$, $\text{Fe}^{2+}(d^6)$, $\text{Co}^{2+}(d^7)$, etc., fit well with this conclusion; there are no perovskite multiferroics with d^0 , d^1 , d^2 , and d^{10} configurations.

Of special importance is also the fact that some d^n ions with $n = 3, 4, 5, 6$, and 7 , dependent on the ligands of the octahedral environment, may produce two types of magnetic centers, high-spin (HS) and low-spin (LS), and in d^6 case there maybe also intermediate spin (IS) states (d^3 has two spin configurations in the one-electron excitation). According to the analysis (Bersuker, 2012), only d^5 systems follow the necessary condition of potential multiferroics in both spin states, but the PJTE condition of instability and the magnetic moments are different in these two cases. For d^3 , d^4 , d^6 , and d^7 ions only one of the two spin states may serve as a candidate of potential multiferroics. On the other hand, in many cases the two spin states are close in energy, producing the mentioned above well-known phenomenon of transition metal *spin crossover* (SCO), in which case the system can be relatively easily transferred from one spin state to another by external perturbations like heat, light, and magnetic fields. Since, as shown above, the change of the spin state also changes the possibility of ferroelectric polarization, the SCO in some perovskite crystals is simultaneously a magnetic-ferroelectric (multiferroic) crossover (MFCO). This coexisting magnetic, ferroelectric, and spin-crossover phenomena opens a variety of new possibilities to manipulate the properties of the system with exciting novel functionalities to electronics and spintronics.

In addition to many examples that confirm the (outlined by the PJTE theory) necessary conditions of multiferroicity (see, e.g., Barone and Picozzi, 2015), several papers reported observing also the predicted magnetic-ferroelectric spin-crossover effect (Domracheva et al., 2013; Raymond et al., 2014; Weston et al., 2016), and it was also shown that in BiCoO_3 the ferroelectric

polarization is greatly enhanced when the Co^{3+} ion is in the high-spin state, as compared to the nonmagnetic state with the Co^{3+} ion in the low-spin configuration (Weston et al., 2016). The authors demonstrated also the predicted *electric magnetization* (Bersuker, 2012, 2013b), when by means of induced polarization the spin state changes from low-spin ($S = 0$) to high-spin ($S = 2$). They concluded that in contrary to the widespread belief, “unpaired electron spins actually drive ferroelectricity, rather than inhibit it, which represents a shift in the understanding of how ferroelectricity and magnetism interact in perovskite oxides” (Weston et al., 2016). This conclusion follows directly (and exclusively) from the above PJTE theory of ferroelectricity and multiferroicity.

Orientational polarization of solids

If the interactions between the JTEs centers in crystals are not sufficiently strong (at temperatures above the structural phase transitions to the cooperative effects), and in the absence of external perturbations, the local distortions at each center are not fully correlated with the others, and they resonate between the different equivalent orientations controlled by the local multiminimum APES. If the barriers between the minima are not very high, the picture as a whole looks like the local dipole moments performing hindered rotations. Under a uniaxial external perturbation (e.g., strain, stress, or electric field E) the equivalency between the minima of the APES is violated, and the system becomes trapped in one of the minima, or in an orientational controlled linear combination of two or several minima that remain equivalent in the external field, in the same direction for all the PJTE centers under the same perturbation.

In other words, under external perturbations, the induced by the PJTE local dipole moments rotate to adjust along the external field, resulting in *orientational polarization of solids*. It is an essentially novel property, which, similar to orientational polarization of liquids, results in drastically enhanced polarization susceptibility in terms of orders of magnitude (Bersuker, 2015a,b; Polinger and Bersuker, 2017; Bersuker and Polinger, 2020). Remarkably, the possible existence of dielectric crystals with randomly oriented dipole moments (similar to ferromagnetics), which may behave like a polar liquid above its freezing point, was first suggested by P. Debye more than a century ago (Debye, 1912), but not discovered till the recent works (Bersuker, 1966, 2015a,b). Below follow several examples of experimentally observable orientational polarization of solids.

Flexoelectricity

There are many consequences of this orientational effect induced by the multiminimum nature of the APES of systems with JTEs. We show here several examples beginning with polarization of centrosymmetric dielectric solids under a strain gradient, called flexoelectricity. The physical origin of flexoelectricity is, in general, quite transparent: a strain gradient removes the inversion symmetry of the lattice in at least one direction, thus inducing a polar distortion of the charge distribution (see, e.g., Tagantsev and Yudin, 2017). Without JTEs the polarization under the flexoelectric effect in usual ionic crystals is expected to be small, of the order of nCm^{-1} , but the experimental measurements of the flexoelectricity effect in ferroelectric systems show that it can be much larger than the theoretical predictions by 3–4 orders of magnitude (Ma and Cross, 2006; Ma, 2010; Nguyen et al., 2013; Zubko et al., 2013). The largest effect is obtained in the paraelectric phase of BaTiO_3 , but it is much smaller in the similar SrTiO_3 crystal, while it approximately follows the theoretical predictions in the majority of other non-ferroelectric crystals. For BaTiO_3 the flexoelectric coefficient f (the component of the tensor coefficient of proportionality between the polarization and strain gradient in the one-dimensional model) decreases significantly when moving from the paraelectric phase to its ferroelectric phases of consequent lower symmetry and becomes “normal” (of the order of magnitude predicted by the theory) in the rhombohedral phase. In essence, the publications on this subject based on displacive theories give no reasonable explanation of this controversy beyond the unproved assumption of different crystal imperfections.

The essential controversies in the origin of flexoelectricity with several orders of magnitude in the difference between its calculated and measured values disappear when the JTE or PJTE leading to orientational polarization, are taken into account. As outlined above, these effects under certain conditions, produce a local dipolar instability and dipolar distortions, which in the free system are of dynamic nature, but become oriented by the gradient of strain. The latter restores a static orientation of the dipoles, in the same direction for all the centers, thus polarizing the centrosymmetric system. This explains the (by-orders-of-magnitude) bigger flexoelectric effect in perovskite crystals as due to the PJTE: restoring a resonating dipole moment (stopping its tunneling between equivalent minima by violating their equivalency) is much easier than separating opposite charges (polarizing) a rigid ionic lattice.

For a demonstration of the orientational polarization, we bring here some numerical estimates of the flexoelectric properties of the BaTiO_3 crystal, for which numerical values of the PJTE induced APES parameters are given in Table 1 (Bersuker, 2015a,b; for a more rigorous treatment, see Polinger and Bersuker, 2017). In the paraelectric BaTiO_3 the Ti ions are (instantly) dipolar displaced in one of the eight equivalent trigonal minima, with tunneling between them (see section “Cooperative PJTE, ferroelectricity”). Any small perturbation in the form of strain gradient makes these PJTE minima nonequivalent, thus violating the conditions of tunneling between them and restoring some of the local dipole moments; the strain gradient acts as a “stop-flow” terminating a part of the tunnelings. Since the strain gradient has the same direction for all the unit cells, this leads to the polarization of the crystal. A rough (qualitative) estimate of the flexoelectric coefficient f in the paraelectric phase of BaTiO_3 , employing the vibronic coupling parameters of Table 1, yields the following relation:

$$f = (d_0/a)(20K_0/T)^{1/2} \quad (5)$$

where we used the expression for the polarization produced by the dipole moments in the minima $P = d_0/a^3$. The dipolar minimum position from Table 1 is $x_0 = \sqrt{3}Q_0$ and the effective (Born) charge of the Ti ion is $Z^* = 8.7e$, hence $d_0 = -\sqrt{3}Z^*eQ_0$. With numerical values of the parameters and K_0 from Table 1 we get the following estimate: $f = -0.43 \cdot 10^{-6} \text{ Cm}^{-1}$.

Thus instead of (and in addition to) producing a polar charge redistribution in a rigid cubic crystal of the order of nCm^{-1} the strain gradient in the paraelectric phase of a PJTE ferroelectric in an orientational polarization recovers the virtual local dipole moments (suppresses their dynamical averaging) inducing the ferroelectric polarization of the order of μCm^{-1} . This removes the main controversy in the theory of flexoelectricity explaining the origin of the 3–4 orders of magnitude larger flexoelectric coefficient f in paraelectric BaTiO_3 as compared with nonferroelectric crystals. As the dynamic JTE and the PJTE are of local origin, the enhanced flexoelectric effect takes place everywhere these effects produce local dipolar distortions, and the density of such JTE or PJTE centers is high enough for experimental observation.

Enhanced permittivity

Similar to flexoelectricity, permittivity of ferroelectric crystals is strongly influenced by the orientational polarization of the dipolar distortions produced by the JTE or PJTE (Bersuker, 2015b). A more rigorous treatment of permittivity of crystals with these effects is given in (Polinger and Bersuker, 2017), but a rough estimation, yielding orders of magnitude, can be obtained directly from the data in Table 1. In the case of permittivity the equivalency between the minima of the APES is violated by an external electric field E , due to which the dynamic polar distortions become trapped in one of the minima (or in an orientational controlled linear combination of the two or several minima that remain equivalent in the field E), in the same direction for all the JTE or PJTE centers. In case of polar distortions this results in polarization of the system, $P_o = \chi_o E$, where χ_o is the contribution to the dielectric susceptibility, which is thus of orientational nature: the virtual dipole moment that resonates between the equivalent minima becomes real, oriented along the field. In addition to this orientational effect there is also the usual displacive susceptibility χ_d . The orientational contribution to the polarization is always much larger than the displacive one, provided there are orientational degrees of freedom in the system (for example, in water $\chi_o = 72$, whereas $\chi_d = 5$). This is quite understandable: similar to the case of flexoelectricity, discussed above, it is much easier to rotate a ready-made dipole along the electric field, than to displacive-polarize a stable polyatomic formation.

Similar to the above rough estimate for the coefficient of flexoelectricity in BaTiO_3 , we get the following relation for the orientational dielectric susceptibility χ_o in the relation $P_o = \chi_o E$, based on the vibronic PJTE theory (Bersuker, 2015b):

$$\chi_o = 2d_0^2/k\Gamma a^3 \quad (6)$$

where $k = 0.1\text{--}1.0$ is an adaptive coefficient. By using the numerical data for the BaTiO_3 crystal in Table 1 we can estimate the numerical value of the susceptibility: $\chi_o = 0.45 \times 10^3\text{--}0.45 \times 10^4$. This agrees well by orders of magnitude with experimental measurements of permittivity in this system.

On the other hand, ignoring the PJTE, the displacive polarization of the unit cell P_d is limited by its stiffness (force constant) K_0 with respect to the polar distortions along the above normal coordinate Q . Hence the electric force $2|e|Z^*E$, producing the dipole moment $|e|Z^*Q$, is compensated by the elastic force K_0Q . Thus, $2|e|Z^*E = K_0Q$ and $P_d = \frac{|e|Z^*Q}{a^3} = \chi_d E$, which leads us to the expression:

$$\chi_d = 2(eZ^*)^2/a^3K_0 \quad (7)$$

Using the same numerical values as above and the K_0 value from Table 1 we get the following estimate: $\chi_d = 1.22$. This yields a typical value expected for permittivity in ionic crystals with just displacive (no orientational) contribution (and in the paraelectric region far from the phase transition). Compared with the value $\chi_o = 0.45 \times 10^3\text{--}0.45 \times 10^4$, obtained above for the orientational contribution, we see that *by taking into account the dynamic PJTE the calculated permittivity of BaTiO_3 increases by more than three orders of magnitude.*

In fact the whole permittivity in the field E up to the orientational saturation at $E = E_m$ is of PJTE origin, acquiring a less-significant displacive-only addition in higher fields. The value of E_m can be estimated from the above expression $E_m \cong k\Gamma/2d_0$. For BaTiO_3 $E_m \cong k \times 1.15 \times 10^7 \text{ V/m}$. It follows that up to this voltage the permittivity is strongly enhanced by the orientational contribution of the dynamic PJTE, reaching the value of polarization $P = d_0/a^3 \cong 0.47 \text{ Cm}^{-2}$ which coincides approximately with that of the ferroelectric phase.

The estimates above demonstrate qualitatively the strong effect of orientational polarization in the properties of crystals with JTEs centers. In a more rigorous consideration (Polinger and Bersuker, 2017) the orientational effect is strongly dependent on the speed of the inter-minima dipoles orientation, characterized by the tunneling splitting parameter Γ in comparison with the local dipole moment d_0 in the minima of the APES, the relative strength of the applied electric field, and even its direction with respect of perovskite crystal axes, illustrated in Fig. 11 (Polinger and Bersuker, 2017).

The enhanced polarization may take place in any dielectric polyatomic formation in the presence of dynamic JTE or PJTE, and the number of such systems in solid, liquid, and gas phases is innumerable. If the centers of the system with local trigonal symmetry are in a degenerate electronic E state, the local $E \otimes e$ type JTE results in three dipolar minima or a trough of dipolar distortions of the Mexican-hat type (Bersuker, 2006). As in the BaTiO_3 case, their contribution to the polarization in electric fields is expected to strongly enhance the permittivity. Similarly, enhancement is expected when the centers with trigonal symmetry are subject to a PJTE.

Fig. 11 Temperature dependence of the dielectric susceptibility χ of the cluster $[\text{BO}_6]$ in perovskite crystals at three directions of the external electric field, $E \parallel [111]$, $E \parallel [100]$ and $E \parallel [110]$, and three absolute values, $E = 0.01\Gamma/d_0$, Γ/d_0 , and $2\Gamma/d_0$, [in units of $\chi_{sc} = d_0^2/(3\Gamma\epsilon_0 a^3)$ with ϵ_0 as the vacuum constant]. The temperature is given in dimensionless units kT/Γ . Reprinted from Polinger V.Z., Bersuker I.B. (2017) Pseudo Jahn-Teller effect in permittivity of ferroelectric perovskites. *Journal of Physics Conference Series* 833: 012012. Copyright 2017 IOP publishing.

Giant electrostriction

Since the electric field along the trigonal axis of BaTiO_3 suppresses the tunneling between the dipolar minima of the APES, trapping all the units of the system in the same kind of trigonal minimum along the whole crystal, the latter will be not only polarized, but also strained in this direction. Similar to permittivity and flexoelectricity, the change in the dimensions of the unit cell in the electric field E , the electrostriction, can be estimated for the BaTiO_3 crystal (Bersuker, 2015b). In fact the electrostriction problem is closely related to the inverse of flexoelectricity: instead of polarization P induced by strain gradient G in flexoelectricity, electrostriction is the strain S (not strain gradient) induced by the polarization. In the one-dimensional model with the electric field and strain along the same trigonal axis of the crystal we have: $S = \gamma P^2$, where γ is the coefficient of electrostriction. More convenient is to measure the strain as a function of the electric field intensity E , $S = \eta E^2$. As shown above, at $E_m \sim (10^6 - 10^7) \text{ Vm}^{-1}$ in the trigonal direction the full orientational ordering of the local unit cell dipoles is reached resulting in the strain $S = Q/a \cong \sqrt{3}Q_0/4 \cong 0.05$. Without the orientational contribution of the dynamic PJTE, from the data above we have: $2|e|Z^*E = K_0Q$ which at $E = E_m$ yields the strain $S \sim 10^{-5}$, a typical value for a regular ionic crystal. Again, as for permittivity and flexoelectricity, the orientational polarization induces giant electrostriction of paraelectric BaTiO_3 , about three orders of magnitude bigger than that in similar systems without the dynamic PJTE, and this effect is in accord with experimental measurements.

Manipulation of solids and 2D systems by influencing their JTEs parameters

The knowledge that the structural instability and distortions of high-symmetry configurations of molecular systems and solids are induced by the JTEs allows one to restore the symmetry of the system by suppressing these effects with external perturbations that influence (modify) the JTEs (vibronic coupling) parameters. Conversely, specific external perturbations can induce the JTEs, producing polyatomic structures with distorted configurations and novel properties. Manipulation of atomic systems by influencing their features induced by the vibronic coupling effects is a novel trend (see in: Bersuker, 2017b, 2019, Gorinchoy et al., 2011, Gorinchoy and Bersuker, 2017, Gudkov et al., 2020); below are several examples.

Inducing the JTE in crystal sublattices

There are two possibilities to manipulate JTE-induced properties of the system by means of external influence targeting the corresponding JTE parameters: (1) destroying the high-symmetry configuration that produces the degeneracy of the electronic state by means of lower-symmetry perturbations; (2) adding or removing valence electrons in a redox process that removes or installs the degeneracy of the state under consideration (without destroying the reference symmetry of the configuration). Low-symmetry external perturbations (e.g., strain, crystal field environment, coordination to lower symmetry groups, electric or magnetic fields, etc.), at first sight, may produce the same kind of distortions, as expected from the JTE, but actually they are essentially different: external perturbation produce *fixed* local distortions without the local JTE dynamics. Obviously, the degeneracies can be manipulated also by adding or removing electronic charge in oxidation, reduction, excitation, coordination, and via other fractional charge transfers (Gorinchoy et al., 2011).

One of these possibilities was recently realized by inducing the JTE in a crystal sublattice of the hexaferrite $\text{BaFe}_{12}\text{O}_{19}$ crystal (Gudkov, 2020). In this crystal structure, all iron ions are in the $\text{Fe}^{3+}(d^5)$ oxidation state with the high-spin configuration ($S = 5/2$),

and they occupy five different crystallographic locations with octahedral, tetrahedral, and bi-pyramidal coordination. In all of them the electronic ground state is orbitally non-degenerate, ${}^6A_1(t_2^3e^2)$, and hence there is no JTE. The authors (Gudkov, 2020) suggested and realized a doping procedure that targets the nondegenerate Fe^{3+} centers, reducing them to $\text{Fe}^{2+}(d^6)$, with the ground state electronic term ${}^5T_2(t_2^4e^2)$ in the octahedral, and ${}^5E(t_2^3e^3)$ in the tetrahedral coordination, both becoming subjects of the JTE. This process was achieved by doping the crystal with electron-donor Ti atoms. It comes out that the dopants target first a tetrahedral site (which is in an easier way of reduction). Therefore, by regulating the concentration of dopants, a whole tetrahedral sublattice of the crystal was transformed in a sublattice with the JTE (the $E \otimes e$ problem) on each of its centers.

Actually, by inducing the JTE in a whole sublattice of the host lattice, we get a modified crystal with properties different from that of the parent crystal. In particular, if the JT centers in the transformed sublattice are sufficiently close to each other, their interaction may lead to the cooperative JTE (see section “Cooperative PJTE, ferroelectricity”) with thermally controlled structural phase transitions within the JTE-modified sublattice. Such a (quite novel) phenomenon with sublattice phase transitions in a complex crystal remains to be explored in more detail. By comparing the properties of the JT modified crystal with the parental crystal, one gets important information about the crystal structure in both of them (Gudkov, 2020).

The formation of the JTE sublattice in the tetrahedral sites of the hexaferrite crystal by means of Ti doping was confirmed by ultrasonic and terahertz-infrared experiments performed at temperatures 2–200 K in external magnetic fields up to 13 T. The vibronic coupling in the tetrahedral $E \otimes e$ type JTE, was analyzed by ultrasound experiments, employing the mentioned above methodology (see section “Ultrasonic exploration”). Using terahertz-infrared spectroscopy made also possible to determine the crystallographic sites of the induced JT centers. The realization of the modified sublattice in a complex crystal seems to be the first case of such manipulation of the JTE by targeted external influence.

Planarization of puckered two-dimensional systems

The origin of instability and distortions of high-symmetry configurations of molecular systems in nondegenerate states as due to the PJTE is already well established with many examples well studied (Bersuker, 2006, 2013a), but manipulation of their structural features based on this knowledge is relatively new and so far applied mainly to planar and quasi planar (two-dimensional (2D) and quasi 2D) systems and their extended forms (see, e.g., Bersuker, 2017b, 2021; Gorinchoy and Bersuker, 2020, and references therein). The enhanced attention to these systems is due to their special structural feature, their out-of-plane distortions in the form of puckering or buckling, which influence all their properties, notably the chemical reactivity, charge mobility, and band gaps. It raises the importance of manipulating this structural feature by means of external implications (perturbations). Many attempts to influence the planarity of 2D systems employ the considerations of atomic orbital hybridization, which correctly illustrates the origin of the out-of-plane distortion effect in some particular cases, but it is insufficient to explain the origin of puckering or buckling in more complicated situations, which cannot be reduced to just hybridizations.

Based on the general proof that all the deviations from high-symmetry configuration of polyatomic systems in nondegenerate states are of PJTE origin, we can find out the main features of the planar configuration of 2D systems that are responsible for the out-of-plan instability and try to influence them by external perturbations. The procedure starts with electronic structure calculations of the ground and low-lying excited states in the planar configuration, their energy, symmetry, MO origin, and the numerical values of the parameters in the condition of instability (1). This gives us the necessary insight on how we can enhance or suppress the distortions, meaning manipulate the puckering or buckling of the system.

In case of the PJTE induced distortions the following manipulation possibilities were suggested: (1) increasing the energy gap Δ between the PJTE active electronic states, e.g., by means of weak coordination with outside systems (van-der-Waals or polarizing external influence); (2) changing the symmetries of the active ground or excited states by removing electrons from, or adding electrons to targeted orbitals, that would nullify the vibronic coupling for the distortion under consideration; (3) changing the numerical value of the constant of the vibronic coupling between the active electronic states by means of partial charge transfer via coordination to outer groups; (4) making targeted chemical substitutions that change the planarity, but do not violate the quasi-2D character of the system; (5) by spectroscopic excitations.

All these possibilities were realized (see: Bersuker, 2017b, and references therein). For illustration, we show here the example of the carbon nitride $g\text{-C}_3\text{N}_4$, where the procedure of planarization was realized by influencing the vibronic coupling parameters via charge transfer by coordination. Graphitic carbon nitride $g\text{-C}_3\text{N}_4$ is a 2D system, which is similar to graphene in many aspects, but unlike graphene, $g\text{-C}_3\text{N}_4$ is not regular planar, it is buckled as shown in Fig. 12.

The PJTE origin of the buckling in this system was studied in detail with the goal to influence it by external perturbations (Ivanov et al., 2015). It was shown that its planar configuration is unstable along the e'' symmetrized displacements for which the coupled HOMO and LUMO responsible for the PJTE instability were revealed by ab initio calculations. With these data and previous experience, the authors suggested suppressing the PJTE and restoring the planar configuration of this system by adding Be^{2+} ions below and above the fragment unit in an inverse sandwich arrangement. The calculations show indeed that the electron acceptor ions change the HOMO-LUMO positions thus quenching the PJTE and flattening the system. Fig. 13 shows the optimized structures of both the fragment unit and the extended sheet of $g\text{-C}_3\text{N}_4$ with appropriately positions of the Be^{2+} ions, which restore the planar configuration, showing also the electronic band structure. Similar planarization procedures involving appropriate external influencing the PJTE parameters were carried out on a series of other 2D systems (see: Bersuker, 2017b, and references therein).

Fig. 12 Buckled 2D structure of graphitic carbon nitride $g\text{-C}_3\text{N}_4$ shown in top and side view. Here and below the gray, blue, and white spheres represent carbon, nitrogen, and hydrogen atoms, respectively. Conclusion

The definition of the JTEs, followed by illustrative examples of some of their more recent applications to the study of structure and properties of polyatomic systems, with examples of applications to local and cooperative properties of solids shows that presently these effects are unalienable features of condensed matter. The theory of JTEs continues developing, and their implication in observable properties is rapidly expanding. All the four JTEs are of local origin, steaming from the specifics of the electron-nuclear (vibronic) interactions. Of them, the best known is the JTE, less known, but already in wider use, is the PJTE, while the exploration of the hidden effects, $h\text{-JTE}$ and $h\text{-PJTE}$, just started. From the most novel applications to condensed matter, local and cooperative properties of crystals are most influenced, the latter including ferroelectricity, multiferroicity, and a novel property of solids, orientational polarization. Quite new is also the developing trend of manipulation of polyatomic properties via influencing their JTEs parameters by means of external perturbations.

Abstract

The Fermi surface separates occupied from unoccupied states in momentum space at zero temperature. For free electrons, the Fermi surface is a sphere, but those of real metals exhibit a spectacular range of topologies. Knowledge of those Fermi surface topologies is the key to understanding the dynamical properties of electrons in metals. An arsenal of ingenious experimental techniques has been developed to reveal the Fermi surfaces of a wide range of materials. This article explores some of these methods, providing a theoretical background and an overview of how the experiments are carried out. The strengths and weaknesses of the different experimental approaches are summarized.

Key points

- Motivate the experimental determination of the Fermi surface.
- Describe the techniques which are able to measure the Fermi surface, with examples.
- Discuss the strengths and weaknesses of those techniques.

Introduction

An isolated atom can meaningfully be thought of as being composed of a positively charged ion core (comprising the nucleus of neutrons and protons as well as the most tightly bound electrons) surrounded by a small number of more loosely bound valence electrons (Chambers, 1966). The atoms in a crystalline solid are sufficiently close together for the wavefunctions of valence

[☆]*Change History:* October 2022. SB Dugdale updated the chapter.

electrons, on one ion core, to overlap with those of its neighbors, allowing the electrons in a metal to move from one ion to the next. These mobile electrons are the conduction electrons of the metal, and one can get a surprisingly good description of the motion of these electrons by only considering the motion of a single electron in the average distribution of all the other electrons in the solid. Perhaps even more surprisingly, substantial insight can be gained by solving the simplest quantum mechanical model of electrons confined to a box (with periodic boundary conditions) in which the energy eigenfunctions are plane waves with eigenvalues which depend quadratically on the (crystal) momentum of the electron. Since electrons are fermions, the Pauli exclusion principle permits each discrete momentum state allowed by the periodic boundary conditions to be filled by (at most) two electrons of opposite spin. Once all the electrons in the crystal have been accommodated, the resulting surface in reciprocal space which separates occupied from unoccupied momentum states at zero temperature is called the Fermi surface (Dugdale, 2016). For free electrons the Fermi surface is simply a sphere. When the interaction between the electrons and the lattice of ion cores, and indeed the correlations between electrons are taken into account, the Fermi surface continues to exist, but, in general will not be spherical and the electrons will behave as though they have masses different from the free-electron mass.

The significance of the Fermi surface lies in the fact that the electrical and thermal properties of a metal are essentially determined by a tiny fraction of its electrons, namely those that lie at or very close to the Fermi surface. The dynamical properties of those electrons depend on where the electron is on the Fermi surface, which means determining the shape of the Fermi surface is a crucial step in understanding the properties of a metal (Dugdale, 2016).

The development of density functional theory (DFT), and its practical implementation in widely available computer codes, has facilitated the calculation of electronic band structure. Theoretical predictions for the topologies of Fermi surfaces have been able to provide great insight. Nevertheless, the experimental determination of Fermi surface remains vitally important as a test of the predictive capability of those calculations, particularly when the presence of strong electron correlations precludes a conventional DFT description.

Quantum oscillations

The phenomenon of quantum oscillations is most easily understood within a semi-classical picture. The classical motion of a charged particle in the presence of a magnetic field B , will be helical in real space. Thus in reciprocal (momentum) space the electron will trace out a circular path. The angular frequency of the motion, ω_c , is called the cyclotron frequency and is given by

$$\omega_c = \frac{eB}{m^*}, \quad (1)$$

where e is the charge on the electron and m^* is the cyclotron mass (which for a free electron is the same as the free-electron mass, m_e). While any cyclotron radius is classically allowed, the necessity of the quantum mechanical wavefunction to be single-valued means that only a discrete set of orbits are permitted. The Bohr-Sommerfeld quantization of the motion of the electron restricts the areas of real space orbits, in the plane perpendicular to the magnetic field, to those which contain an integer multiple of the flux quantum. The area of the n^{th} allowed orbit in real space, A_n , is given by

$$A_n = \left(n + \frac{1}{2}\right) \frac{h}{eB}, \quad (2)$$

where e is the charge on the electron and h is Planck's constant.

The circular orbits in reciprocal space will be similarly quantized; they are called 'Landau levels' and will have areas A_n^* , given by

$$A_n^* = \left(n + \frac{1}{2}\right) \frac{2\pi eB}{\hbar}. \quad (3)$$

Since there is no additional quantization of the orbits parallel to the magnetic field, in three dimensions these semi-classical orbits lie on 'Landau tubes', as shown in Fig. 1. The Fermi surface, which was quasi-continuous in zero magnetic field, is now constrained to lie on these Landau tubes.

The density of states will be a set of sharp δ -function-like peaks, separated in energy by $\hbar\omega_c^*$. If the energy of an electron state on one of these Landau tubes is below the chemical potential, the state will be occupied. As the magnetic field B is changed, the separation of the Landau levels will change, and as a Landau level passes through the chemical potential μ , the density of states at the chemical potential will change. The chemical potential is identical to the Fermi energy at zero temperature, but at low temperature in a metal the Fermi energy is a very good approximation to the chemical potential (and the two are often used interchangeably, even if this is not strictly correct).

Consider a two-dimensional free-electron gas of non-interacting electrons at low temperature and in zero magnetic field. The Fermi surface will be a circle with a radius equal to the Fermi wavevector, k_F , enclosing an area $A_{\text{FS}}^* (= \pi k_F^2)$ containing occupied states. In the presence of a magnetic field B , the allowed electron states will coalesce onto Landau levels, the energy separation of which will increase with B such that successive Landau levels will pass through the chemical potential when they have an area A_{FS}^* . As each Landau level is depopulated, electrons will be transferred to and accommodated in lower Landau levels, this being permitted since the degeneracy of each level is proportional to B . Consider a situation in which at some magnetic field, B_n , the n^{th} Landau level is coincident with the Fermi surface i.e., it has an area A_{FS}^* . If the magnetic field is changed so that the separation between Landau levels changes then at some new magnetic field, B_{n+1} , the next $((n+1)^{\text{th}})$ Landau level will also have the same area, A_{FS}^* . For that to be true, then

$$A_{\text{FS}}^* = \left(n + \frac{1}{2}\right) \frac{2\pi eB_n}{\hbar} \quad (4)$$

Fig. 1 A spherical Fermi surface (dashed line) in a magnetic field together with some Landau tubes.

and

$$A_{\text{FS}}^* = \left(n + 1 + \frac{1}{2}\right) \frac{2\pi e B_{n+1}}{\hbar}. \quad (5)$$

It follows that

$$A_{\text{FS}}^* \left(\frac{1}{B_{n+1}} - \frac{1}{B_n} \right) = \frac{2\pi e}{\hbar}, \quad (6)$$

and therefore the change in (inverse) magnetic field ($\Delta(1/B)$) needed to make two consecutive Landau levels have areas which coincide with the Fermi surface is

$$\Delta \left(\frac{1}{B} \right) = \frac{2\pi e}{\hbar A_{\text{FS}}^*}. \quad (7)$$

If measurements of $\Delta \left(\frac{1}{B} \right)$ can be made by determining the period of oscillations as a function of inverse magnetic field as B is changed, then Eq. (7) (the so-called ‘Onsager relation’ (Onsager, 1952)) can be used to infer the area of the Fermi surface, A_{FS}^* . Almost all of the physical properties of a metal are sensitive to the density of states at the chemical potential and therefore it is to be expected that there will be modulation of these physical properties as successive Landau levels pass through the chemical potential.

Moving from two to three dimensions, it can be shown using the stationary phase approximation that the contributions of different non-extremal areas will cancel such that the signal is dominated by the extremal areas. The extremal areas are usually identified as distinct frequencies (and their harmonics) in the Fourier transform of the measured oscillations. In a three-dimensional metal, a measurement will provide information about extremal (maximal and minimal) Fermi surface cross-sectional areas in planes perpendicular to the magnetic field. For a spherical Fermi surface, such a measurement immediately provides the equatorial area of the Fermi surface and measurements with the magnetic field aligned along different crystallographic directions would always yield the same extremal cross-sectional area. For a cylindrical Fermi surface (Fig. 2), the extremal area will increase like $1/\cos \theta$ as the magnetic field is moved away from the cylindrical axis. For more complicated topologies (e.g. Fig. 3), or when more than one sheet of Fermi surface exists (owing to more than one band crossing the Fermi energy), it is necessary to try and solve the inverse problem of extracting the Fermi surface topology from the set of measured extremal areas as a function of the magnetic field direction (Mueller and Priestley, 1966). In practice, the experimentally extracted extremal areas are compared with predictions of DFT calculations (Rourke and Julian, 2012). For example, in their measurement of the Fermi surface of the nodal-line semi-metal CaAgAs, Kwan et al. (2020) were able to match their quantum oscillations measurements as a function of angle to the geometry of a toroid.

Experimental realization

In practice, many measurable quantities will exhibit quantum oscillations, including the magnetic susceptibility (de Haas-van Alphen effect) (Shoenberg 1984), resistivity (Shubnikov-de Haas effect), specific heat and magnetostriction (lattice deformation in

Fig. 2 For a cylindrical Fermi surface with cross-sectional area A , the extremal area increases as $\frac{A}{\cos \theta}$ the magnetic field is rotated by θ away from the cylindrical axis.

Fig. 3 Extremal orbits on the Fermi surface. The white orbit shows the single extremal orbit when the magnetic field parallel to k_y . When the field is parallel to k_z there will be both a maximum orbit (dashed black line) and a minimum orbit (solid black line).

the presence of magnetization). The observation of quantum oscillations in metals relies on very low temperatures (typically less than 1 K), very large magnetic fields (typically greater than 10 T) and for the electron mean-free-path to be very long (typically greater than 1000 Å, implying a residual resistivity of less than $1 \mu\Omega \text{ cm}$). The development of several laboratories around the world which are dedicated to providing high magnetic field environments (both DC and pulsed) has meant that the restriction on sample purity can be less stringent.

De Haas-van Alphen oscillations are usually measured using a field modulation technique in which a modulation field of a few mT and a frequency of a few Hz is applied on top of a background field (Bergemann et al., 2003). This is combined with torque cantilever magnetometry in which the sample is attached to one end of a cantilever which acts as one plate of a capacitor (Sheikin et al., 2003). The torque in the magnetic field bends the cantilever with respect to the fixed capacitor plate, changing the capacitance. By using a capacitance bridge, such an arrangement can detect changes to less than one part in a million (Hall et al., 2001). Piezo-resistive cantilevers (Rossel et al., 1996), combined with resistance bridges have also been used (Cooper et al., 2003).

Given that the energy separation of two neighboring Landau levels is $\hbar\omega_c^* = \frac{\hbar e B}{m}$, if $k_B T$ becomes comparable with that separation then the amplitude of the oscillations will be strongly suppressed. One term in the Lifshitz-Kosevich formula describes the temperature damping of the oscillations by a factor $\left(\frac{X}{\sinh X}\right)$, where $X = \left(\frac{2\pi^2 k_B T m^*}{\hbar e B}\right)$ (Lifshitz and Kosevich, 1956; Shoenberg, 1984). By tracking the amplitude of the oscillations as a function of temperature, very accurate quasiparticle effective masses can be determined. The effective mass m^* measured in a quantum oscillations experiment will be renormalized by both electron-electron and electron-phonon interactions (Kohn, 1961; Quader et al., 1987). The presence of disorder (for example from impurities) will introduce a finite relaxation time, τ , to the quasiparticles which will broaden the Landau levels. This broadening in energy can be estimated from the Heisenberg Uncertainty Principle as being of the order of $\hbar/\tau$. A full treatment shows that owing to a finite τ , the amplitude of the oscillations will be reduced by a factor proportional to $e^{(-\pi/\omega_c \tau)}$, and when its full form is considered in the Lifshitz-Kosevich formula, it is known as the 'Dingle factor' (Shoenberg, 1984). This factor enables the relaxation time τ to be extracted. There will be a further reduction in the amplitude of the oscillations due to electron spin. In the presence of a magnetic field, the spin-up and spin-down electrons will have separate Landau tubes. This will lead to interference between oscillations coming from electrons of opposite spin which reduces the amplitude of the signal. Further details can be found in Shoenberg (1984).

The observation of 'giant' orbits in de Haas-van Alphen measurements of Mg which were larger than the cross-sectional area of the Brillouin zone (Priestley and Shoenberg, 1963) were explained by Cohen and Falicov (1961) in terms of electrons tunneling from one orbit on one section of the Fermi surface to another separated from it by a small energy gap, ϵ_g . This was referred to as 'magnetic breakdown'. It was subsequently shown that the criterion for magnetic breakdown to occur is that $\hbar\omega_c \geq \epsilon_g^2/E_F$, where E_F is

the Fermi energy (Blount, 1962). In practice, this means that magnetic breakdown could occur in magnetic fields of the order of 1 T (Shoenberg, 1984).

Shubnikov-de Haas oscillations of the (magneto)resistivity in metals are often weak (Shoenberg, 1984) and challenging to observe and the theory is quite complicated (Adams and Holstein, 1959). The effect is easier to observe in semiconductors and semimetals. As an example, the observation of Shubnikov-de Haas oscillations in ‘magic-angle’ twisted bilayer graphene have confirmed the presence of a small Fermi surfaces which emerges from the correlated insulating state (Cao et al., 2018). In sample geometries where there is limited scope for pick-up coils, such as inside pressure cells, measurements of Shubnikov-de Haas oscillations are favored. Putzke et al. (2016) were able to follow the behavior of the effective mass m^* in $\text{YBa}_2\text{Cu}_4\text{O}_8$ under hydrostatic pressure (up to about 0.8 GPa) and correlate this with the superconducting critical temperature.

Angle-resolved photoemission

Angle-resolved photoemission spectroscopy (ARPES) can measure the single-particle spectral function, $A(\mathbf{k}, \omega)$, which contains information not only about the band structure and Fermi surface, but also about the self-energy $\Sigma(\mathbf{k}, \omega)$, since the real part of the self-energy will change the centers of the bands and the imaginary part will broaden them. In the last 30 years, ARPES has developed into a powerful tool for revealing Fermi surfaces and providing significant insight into the impact of electron correlations on electronic structure (Sobota et al., 2021).

In the photoelectric effect, the energy of a photon which is incident on the surface of a material is absorbed by an electron which then escapes from the material’s surface. In an ARPES experiment, by measuring properties of the electron outside the material, the kinematics of photoemission can be used to infer the binding energy, E_B , and the crystal momentum $\hbar\mathbf{k}$ of the electron prior to its emission.

An ARPES experiment requires a monochromatic source of photons, typically in the UV regime which then impinge on the surface of a single-crystal sample, as shown in Fig. 4. Some fraction of the photoelectrons, which are emitted in all directions, are then detected by an analyzer. The two-dimensional detector of the popular hemispherical analyzer chromatically disperses the electron beam such that the kinetic energy, E_{kin} can be recorded along one spatial dimension and the angular distribution along the other (Mårtensson et al., 1994). The emission angle (θ, ϕ) is defined such that the polar angle θ is described with respect to the surface normal, and the azimuthal angle ϕ is usually defined relative to a crystallographic direction. Two important relationships can be derived by considering the conservation of energy and momentum

$$E_B = h\nu - \Phi - E_B - E_{\text{kin}}, \quad (8)$$

where Φ is the work function, and

$$\hbar\mathbf{k}_{\parallel} = \sqrt{2mE_{\text{kin}}} \sin \theta, \quad (9)$$

where $\hbar\mathbf{k}_{\parallel}$ is the crystal momentum parallel to the surface in the extended zone scheme and where the photon momentum (negligible in the UV regime) has been neglected in Eq. (9). The parallel component, $\hbar\mathbf{k}_{\parallel}$ is conserved (up to an in-plane reciprocal lattice vector $\mathbf{G}_{\parallel}$, due to the discrete in-plane translational invariance). Although the crystal momentum perpendicular to the surface, $\hbar\mathbf{k}_{\perp}$, is not conserved, it is usually possible to infer it if one assumes that the final-state dispersion of the photoelectron inside the crystal can be parameterized using a free-electron dispersion shifted by a so-called ‘inner potential’. It should be noted that in truly 2D materials, $\hbar\mathbf{k}_{\perp}$ is not relevant.

Spin-resolved ARPES measurements are also feasible (Osterwalder, 2006). If a spin detector (e.g., a Mott polarimeter) is coupled to the analyzer, spin- and angle-resolved photoemission spectroscopy is possible. For example, in the 3D topological insulator $\text{Bi}_{1-x}\text{Sb}_x$, the spin-polarized nature of the surface states has been observed using such a Mott detector (Hsieh et al., 2010).

Fig. 4 An ARPES experiment. Photons, typically from a synchrotron source impinge on a sample, ejecting a photoelectron which is emitted at polar and azimuthal angles (θ, ϕ) , respectively. The electron is detected by the hemispherical analyzer.

Experimental realization

Synchrotron sources provide photon energies which are continuously tunable from the vacuum ultraviolet (VUV) through to hard X-rays (although not on the same synchrotron beamline). This is an important advantage of a synchrotron photon source, since it permits measurements to be made at different energies and polarizations, both of which influence the matrix elements for the photoemission process (Bansil and Lindroos, 1999). A tunable photon source also allows the k_z dispersion to be investigated. Photoemission is surface sensitive, the escape of the photoelectron being limited by its inelastic mean-free-path. This is strongly dependent on the incident photon energy, but only varies weakly from one material to another, giving rise to the so-called ‘universal curve’ shown in Fig. 5 (Seah and Dench, 1979). At typical photon energies from UV sources, the inelastic mean-free-path is less than 1 nm. In order to obtain bulk information, a necessary, but not sufficient condition, is that the sample surface is atomically flat and clean. The presence of surface states and/or surface reconstruction would still prevent a bulk measurement. Therefore surface preparation is key and treatments such as sputtering and annealing are often employed if the crystal cannot be cleaved in situ to expose a pristine surface. Measurements at temperatures of ~ 10 K are commonplace, and ARPES has even successfully been performed below 1 K (Borisenko et al., 2010). Once the surface has been prepared, it needs to be kept at pressures of the order of 10^{-9} Pa. An estimate of the time (in seconds) for a monolayer of a highly reactive gas (e.g., oxygen) to form on a clean transition metal surface under a pressure of p Pa is of the order of $t_m(s) \approx 2 \times 10^{-4}/p$; this is only ~ 2 days at $p \sim 10^{-9}$ Pa (Hofmann, 2013).

In practice, higher cross-sections and better resolution for a given resolving power mean that the majority of experiments are conducted in the VUV range. The typical beam spot size is between 10 μm and 100 μm , although by focusing the photon beam onto an area of the sample of the order of a 100 nm wide, recent advances in so-called nano-ARPES offer the possibility of probing the electronic structure of nano-scale samples, single domains within a crystal, and permitting spatially resolved measurements by raster scanning across the surface of a sample (Avila and Asensio, 2014).

UV lasers can also be used to produce high photon fluxes with great energy stability and energy/momentum resolutions, with spot sizes smaller than 5 μm having been achieved. Gas discharge lamps combined with a monochromator can also be used as a photon source, with spot sizes typically of about 1 mm, although smaller sizes down to about 200 μm are possible.

The ability of ARPES to rapidly deliver great insight into the Fermi surface topologies of new classes of material in the form of beautiful images and multi-dimensional datasets which contain a wealth of information about the nature of their electronic structure is most certainly one of its great strengths. Such has been its success that it has become almost commonplace to expect that ARPES can deliver many important answers to questions about the underlying physics at play in a material. The recent exposition of the Fermi surface of the Kagome-lattice superconductor KV_3Sb by Luo et al. (2022) showcases how such experiments can reveal not only the Fermi surface in exquisite detail, but also evidence of charge-density-wave reconstruction including the extraction of the size and anisotropy of the induced gaps, signatures of electron-phonon coupling such as kinks in the band dispersions, and self-energy effects in the electronic structure. In another topological Kagome metal, CsV_3Sb_5 , ARPES measurements have been able to probe the role of van-Hove singularities in electronic symmetry breaking (Kang et al., 2022). Being able to follow electronic structure through phase transitions governed by some control parameter other than temperature is a highly desirable objective. By subjecting a sample of Pr-doped Ca_2RuO_4 to uniaxial strain, Riccò et al. (2018) were able to suppress the Mott-insulating phase and induce metallicity as evidenced by the appearance of a Fermi surface.

Time- and angle-resolved photoemission spectroscopy (trARPES) can provide new insights into the dynamics and out-of-equilibrium behaviors of electrons in solids. This pump-probe approach typically uses a femtosecond infra-red laser pulse to first excite the sample which is subsequently probed by the UV pulse at some time delay with respect to the excitation. An example of this approach is a study of the dynamics associated with the melting and recovery of a charge-density wave (CDW) (Zong et al., 2019). The investigation revealed the re-appearance (upon melting) of the nested parts of the Fermi surface of LaTe_3 and their subsequent disappearance as both the CDW coherence and the gap are re-established. In a spin, time and angle-resolved study, the pump-probe measurements of Jozwiak et al. (2016) were able to reveal spin texture in the unoccupied bands above the Fermi energy in Bi_2Se_3 .

Fig. 5 The depth from which a photoelectron can escape is limited by its inelastic mean-free-path. This ‘universal curve’ as a function of electron’s kinetic energy is based on data from Seah and Dench (1979).

ARPES measurements are usually made by rotating the sample with respect to a fixed analyzer. In order to scan the sample surface in real space to locate regions which are of interest (for example, a particular domain) before performing ARPES, either the sample has to be moved with respect to the photons which are confined to a small spot size, or by using an instrument which permits the both real space and k -space to be imaged using strong electric fields to extract the electrons (Cattelan and Fox, 2018). However, there is another category of instrument which is generally referred to as an energy-filtered photoemission electron microscope (EF-PEEM), or more succinctly as a ‘momentum microscope’. Here, the photoelectrons are accelerated into a column containing electron optical elements, as well as apertures in the image plane which can be used to select μm -sized regions of a sample. The optical elements can be adjusted to image either in real-space or reciprocal space. This means that interesting regions of the sample in real space can be selected before switching to reciprocal space where ARPES is carried out by acquiring images of the available portion of k -space at a series of different kinetic energies. The Fermi surface can be mapped by acquiring images of the spectral weight at the Fermi energy (Cattelan and Fox, 2018). One clear advantage of EF-PEEM instruments over conventional ARPES for FS measurements is that all of the available $\mathbf{k}_{\parallel} = (k_x, k_y)$ momentum space is measured simultaneously (this sometimes being referred to as ‘full wavevector ARPES’) i.e., a 2D image of the FS is acquired at once.

Many more details about instrumentation and the current capabilities of ARPES, can be found in the review by Iwasawa (2020).

Angle-dependent magnetoresistance oscillations

In materials whose electronic structure is quasi one- or two-dimensional, the magnetoresistivity (which describes the change in the resistivity in an external magnetic field) for currents along the high-resistivity axis, is particularly sensitive to the direction of the applied magnetic field. In the previous section, Shubnikov-de Haas quantum oscillations in the resistivity and the connection between the period of those oscillations (in inverse magnetic field) and the extremal area of the Fermi surface has been described. The non-extremal orbits, while not contributing to the oscillations, do generate a non-oscillatory background magnetoresistance which can be quite sensitive to the direction of the magnetic field (Blundell and Singleton, 1996a, 1996b). In some cases, very large angle-dependent magnetoresistance oscillations (AMROs) can be found at fixed magnetic field.

AMROs can be measured experimentally by rotating the sample in a fixed magnetic field. They can provide complementary information to quantum oscillations since the signal comes from all electrons on the Fermi surface, not just those associated with the extremal orbits. Since AMROs don’t come from Landau levels passing through the chemical potential, they should be observable at much higher temperatures and much lower magnetic fields than quantum oscillations. Scattering from impurities will, however, suppress the oscillations. AMROs should be visible if $\omega_c\tau \gg 1$, where τ is the relaxation time (inverse scattering rate). In practice, however, the usefulness of this powerful technique is limited to lower dimensional electronic structures (1D and 2D) and to metals with only one or two sheets of Fermi surface since analysis becomes difficult when there are contributions from more than one.

Types of oscillation

In general, the different kinds of oscillations that can be found in quasi-1D and quasi-2D materials have been given different names (for example, the ‘Danner-Kang-Chaikin’ oscillations seen in quasi-1D metals (Danner et al., 1994)). A description of the types of oscillations associated with some of these can names can be found in Goddard et al. (2004) and an excellent description of AMROs in quasi-one-dimensional metals can be found in Blundell and Singleton (1996a, 1996b).

As an example, considered a quasi-2D Fermi surface such as a warped cylinder, as shown in Fig. 6. On the simplest level, for such a Fermi surface there will be a maximum in the magnetoresistance whenever the magnetic field is oriented such that the Fermi surface cross-sectional areas in the plane perpendicular to the field are all the same. The phenomenon can be understood from a semi-classical perspective within the relaxation time approximation in which oscillations as a function of the angle of the magnetic

Fig. 6 When the magnetic field B is rotated away from the cylindrical c -axis by a Yamaji angle (θ_Y), the c -axis conductivity disappears because the c -axis component of the Fermi velocity v_{Fz} averages to zero over the cyclotron orbit. Adapted from Bergemann C, Mackenzie AP, Julian SR, Forsythe D, Ohmichi E (2003) Quasi-two-dimensional fermi liquid properties of the unconventional superconductor Sr_2RuO_4 . *Advances in Physics* **52**: 639–725. <https://doi.org/10.1080/00018730310001621737>.

Fig. 7 When the magnetic field B is parallel to the cylindrical c -axis, all the cyclotron orbits are different, as indicated by the extremal black and white orbits shown in (a). When the field is rotated to a Yamaji angle, as shown in (b) and (c), all the Fermi surface cross-sections perpendicular to the magnetic field have the same area.

field originate from the way the components of the quasiparticle velocity is averaged over the cyclotron orbits which occur at a particular orientation of the magnetic field, θ_Y , known as a ‘Yamaji angle’, as indicated in Fig. 6.

Consider the warped cylindrical Fermi surface shown repeated over several Brillouin zones in Fig. 7. The applied magnetic field B will make the electrons execute cyclotron orbits on the Fermi surface in planes perpendicular to the field. When the magnetic field is rotated away from the high-resistivity axis then at certain angles θ_Y , determined by the shape of the Fermi surface, the areas of *all* orbits will be equal. In such cases, the component of the velocity parallel to the high-resistivity axis will average to zero, and there will be a maximum in the resistivity. These Yamaji ‘magic’ angles are periodic in $\tan \theta$.

Experimental realization

The c -axis resistivity is measured as a function of the direction of the magnetic field. The analysis of AMROs involve the fitting of the experimental data to a parameterization of the underlying Fermi surface. A description of how this can be done efficiently can be found in Bergemann et al. (2003). The measurement of a coherent 3D Fermi surface in a cuprate superconductor by Hussey et al. (2003) is an excellent example of how AMROs can provide important insight. The Fermi surface of $\text{Ti}_2\text{Ba}_2\text{CuO}_{6+\delta}$ was revealed by fitting the oscillations, measured using a single-axis rotator in a magnetic fields of 45 T (provided by a hybrid magnet) and a temperature of 4.2 K, to a parameterized Fermi surface. These AMRO results for the Fermi surface topology were subsequently confirmed by ARPES (Plat   et al., 2005), and quantum oscillations (both Shubnikov-de Haas and de Haas-van Alphen) (Vignolle et al., 2008).

The electron momentum distribution—Compton scattering and positron annihilation

Within the one-electron approximation, the electron momentum distribution (EMD) can be expressed in terms of the one-electron wavefunction $\psi(\mathbf{r})$ as

$$\rho(\mathbf{p}) = \left(\frac{1}{2\pi\hbar}\right)^3 \sum_{\text{occ}} \left| \int \psi(\mathbf{r}) \exp(-i\mathbf{p}\cdot\mathbf{r}/\hbar) d\mathbf{r} \right|^2. \quad (10)$$

The EMD contains information about the occupied states in momentum space and therefore in a metal will possess signatures associated with the presence of the Fermi surface due to the sum being over the occupied momentum states. Experimentally, the EMD can be accessed using Compton scattering and positron annihilation. The main advantage of these experimental techniques is that they are bulk probes which can be used at elevated temperatures and which are not limited by the electron mean-free-path (meaning, for example, that the Fermi surfaces of disordered alloys can be measured (Dugdale et al., 2006)). Compton scattering is a unique probe of the many-body ground state wavefunction.

One significant strength of both techniques is that measurements can be made at elevated temperature, including above room temperature which is required to probe the Fermi surface of paramagnetic Cr (Fretwell et al., 1995). Positrons are susceptible to being trapped by open-volume defects such as vacancies (resulting in a partial or complete suppression of any anisotropy in the

measured distributions (Dugdale and Laverock, 2014)). Compton scattering has no such restriction. Although both techniques measure a projection of the momentum distribution (rather than the distribution itself, as described below), it is straightforward (if time consuming because of the number of projections which must be measured) to tomographically recover the full three-dimensional momentum distribution by combining measurements made along different crystallographic directions (Kontrym-Sznajd and Samsel-Czekala, 2000; Kontrym-Sznajd, 1990).

Both positron annihilation and Compton scattering experiments measure the real momentum $\mathbf{p}$ (as opposed to the crystal momentum $\mathbf{k}$) of the electrons in the material. In the presence of a Fermi surface (such as that of Li whose Fermi surface, calculated from DFT in the non-interacting zero-temperature limit, is shown in Fig. 8), the discontinuities in the momentum distribution arise when the contribution of a band appears or disappears as the band passes through the Fermi energy (at $\mathbf{k} = \mathbf{k}_F$) (see Fig. 9). These will appear not only at $\mathbf{p} = \mathbf{k}_F$, but also at all $\mathbf{p} = \mathbf{k}_F + \mathbf{G}$, where $\mathbf{G}$ is a reciprocal lattice vector. This is illustrated in Fig. 10 in which the EMD, $\rho(\mathbf{p})$, is plotted along the [100] direction. At $\mathbf{p} = \mathbf{k}_F$, the contribution of the 2s band drops to zero, before reappearing in what would be the second Brillouin zone in the extended zone scheme. The two insets in Fig. 10 show these so-called ‘higher momentum components’.

However, it is straightforward to restore the discrete translational invariance of $\mathbf{k}$ -space by bringing the measured densities back into the first Brillouin zone (using the reciprocal lattice vectors) by taking the contributions in higher Brillouin zones and adding them to that in the first Brillouin zone (in a process known as ‘LCW folding’ (Lock et al., 1973)). The discontinuities associated with the partially occupied bands will reinforce constructively, and the contributions from fully occupied bands will combine to give a constant background. In this LCW procedure, the momentum density in $\mathbf{p}$ -space becomes an occupation number in $\mathbf{k}$ -space. Returning to our Li example, the resulting occupation number can be seen in Fig. 11. The Fermi surface will then be visible as a

Fig. 8 The Fermi surface of Li is almost spherical. The X symmetry point on the Brillouin zone is indicated. The program FermiSurfer was used to plot the Fermi surface (Kawamura, 2019).

Fig. 9 The band structure of Li, plotted along the [100] direction in the repeated zone scheme. The tightly-bound lower band is due to the core-like 1s electrons and as such is almost flat (dispersionless). The upper band is due to the (much larger) overlap of 2s electron wavefunctions, resulting in a much more dispersive band. Note that the energy scale has been split since the 1s is a long way below the Fermi energy.

Fig. 10 The electron momentum distribution of Li resolved along the [100] direction. Note that 1 atomic unit (a.u.) of momentum is equal to $1.99285191410 \times 10^{-24} \text{ kg m s}^{-1}$. The two insets (with their ordinate axes scaled by 10^2 and 10^4 , respectively) show how the momentum density for band 2, which decreases to zero at $p = k_F$, reappears to make contributions in the second and third Brillouin zones.

Fig. 11 Occupation number for Li along the [100] direction obtained by LCW folding (Lock et al., 1973) the EMD back into the first Brillouin zone. At the origin (the Γ point), both bands are occupied giving four electrons. The completely occupied 1s band sums to a constant, but the partially occupied 2s exhibits a discontinuity at the Fermi wavevector k_F as the occupation number for that band drops to zero. Note that the Brillouin zone boundary at the symmetry point X is at $(\frac{2\pi}{a})$ in the body-centered cubic lattice of Li.

change in the occupation number. An example of fitting several Fermi surface breaks to an occupation number reconstruction from several high-resolution Compton profiles measured on the high-entropy alloy NiFeCoCr can be found in Robarts et al. (2020). Since the Fermi surface is highly smeared due to the extreme compositional disorder (the atoms are randomly distributed on an underlying face-centered cubic lattice), the smeared Fermi breaks can be clearly resolved, and the local contributions to the electron mean-free-path determined across the Fermi surface from the degree of smearing.

Compton scattering

Following Schülke (2007), the basic kinematics of an inelastic scattering experiment are shown in Fig. 12. A photon of energy $\hbar\omega_1$, wavevector $\mathbf{K}_1$, and (unit) polarization vector $\mathbf{e}_1$ scatters at an angle θ off a target which is characterized by a state vector $|i\rangle$ and energy E_i , resulting in a photon of energy $\hbar\omega_2$, wavevector $\mathbf{K}_2$ and polarization vector $\mathbf{e}_2$. The target is left in a final state $|f\rangle$ with an energy E_f . Conservation of energy and momentum imply that an energy $\hbar\omega$, given by $\hbar\omega \equiv \hbar(\omega_1 - \omega_2) = E_f - E_i$, and a momentum $\hbar\mathbf{q} \equiv \mathbf{K}_1 - \mathbf{K}_2$ are transferred to the target. As long as $\omega \ll \omega_1$, $q \approx 2 K_1 \sin(\theta/2)$ (Schülke, 2007).

In a Compton scattering experiment, monoenergetic incident photons are scattered by the electrons in the sample and the energy distribution of the scattered photons is measured to a resolution $d\hbar\omega_2$ within some solid angle $d\Omega_2$. This is the double differential scattering cross-section, which can be expressed in the non-relativistic limit as (Schülke, 2007):

$$\frac{d^2\sigma}{d\Omega_2 d\hbar\omega_2} = r_0^2 |\mathbf{e}_1 \cdot \mathbf{e}_2|^2 \left(\frac{\omega_2}{\omega_1} \right) \sum_{i,f} p_i \left| \left\langle f \left| \sum_j e^{i\mathbf{q} \cdot \mathbf{r}_j} \right| i \right\rangle \right|^2 \delta(E_f - E_i - \hbar\omega), \quad (11)$$

where p_i is the probability of the initial state $|i\rangle$ and r_0 is the classical electron radius. The sum over j is over all the electrons in the system.

Fig. 12 Compton scattering of a photon with wavevector $\mathbf{K}_1$, unit polarization vector $\mathbf{e}_1$ and frequency ω_1 by an angle θ by a moving electron in an initial state $|i\rangle$, leaving it in a final state $|f\rangle$.

Fig. 13 The Compton profile $J(p_z)$ of Li, resolved along the [100] direction.

In order to probe single-particle properties (rather than their collective behavior), q^{-1} must be much smaller than the distance between the electrons. For the properties to be representative of the ground state, the scattering process should be fast such that the energy transfer $\hbar(\omega_1 - \omega_2)$ is sufficiently high to prevent the remaining system of electrons from rearranging itself. This is usually described within the so-called ‘impulse approximation’ which is valid when the energy transferred in the scattering process is much larger than the binding energies of any electrons involved; the other electrons are mere spectators since the scattering occurs on a very short timescale on the order of 10^{-19} s.

If the photons were scattering off stationary electrons then the scattered photons would all have the same energy given by the usual Compton formula [Compton \(1923\)](#). However, the electrons have finite momentum and therefore the photon energies will be Doppler-broadened and the distribution of energies recorded at that fixed angle can be related to the momentum distribution of the electrons along the scattering vector integrated over the two orthogonal momentum components. It can be shown that

$$\frac{d^2\sigma}{d\Omega_2 d\hbar\omega_2} \propto \int \int \rho(\mathbf{p}) dp_x dp_y, \quad (12)$$

where $\rho(\mathbf{p})$ is the momentum density. The quantity

$$J(p_z) \equiv \int \int \rho(\mathbf{p}) dp_x dp_y \quad (13)$$

is called the Compton profile; it is the projection of the momentum density along the scattering vector. A detailed description of the theoretical background can be found in Refs. ([Cooper et al., 2004](#); [Eisenberger and Platzman, 1970](#); [Eisenberger and Reed, 1974](#); [Ribberfors, 1975a, 1975b](#)).

Revisiting the Li example, its Compton profile along the [100] direction is shown in [Fig. 13](#). In this case, the fully occupied first band gives rise to a broad, smooth, Gaussian-like distribution, whereas the almost spherical Fermi surface contributes an inverted

Fig. 14 Schematic of a Cauchois-type high-resolution Compton spectrometer, based on Itou et al. (2001).

parabola when it is integrated over two momentum components. However, the Fermi break k_F can still be identified (in Fig. 13 at about $p \sim 0.6$ ($2\pi/a$)) and the higher momentum components are just visible as bumps at momenta outside the first Brillouin zone. If the LCW procedure were applied to the Compton profile, a projected occupation number would be obtained.

The two ‘lost’ momentum components can be reconstructed tomographically, typically by measuring 10–30 Compton profiles along different crystallographic directions. With reconstruction techniques based on polynomial expansions, the number of profiles required for a faithful reconstruction can be reduced by carefully choosing the directions.

Experiments are usually performed at synchrotron sources. As an example of an experimental geometry, the Cauchois-type high-resolution Compton spectrometer at SPring-8 (shown in Fig. 14) offers a typical momentum resolution of 0.1 a.u. (Itou et al., 2001) and a photon energy of 115 keV. At these kinds of photon energies, it is clear that it is the bulk being probed. The Compton-scattered photons are dispersed by a bent crystal analyzer and registered on a position-sensitive detector. In some spectrometers, a trade-off can be made between count rate and resolution, and ultra-high resolution measurements (with a momentum resolution of about 0.02 a.u.) measurements have been performed (Schülke et al., 2001).

An excellent example of the kind of information that Compton scattering can provide can be found in Tanaka et al. (2001). Since bcc Li has a martensitic transformation at 75 K (Smith, 1987), quantum oscillatory probing of the Fermi surface is challenging (Hunt et al., 1989). By reconstructing the full 3D EMD from high-resolution Compton profiles, the small anisotropy ($\sim 4\%$) in its Fermi surface has been revealed (Schülke et al., 1996; Tanaka et al., 2001). Moreover, both studies were able to show electron correlation substantially reducing the size of the break Z_k in the momentum density (sometimes called the ‘quasiparticle residue’) at the Fermi surface. Compton scattering has also been able to map out the evolution of the Fermi surface of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ as a function of doping (Sakurai et al., 2011) and expose the possible role of nematicity in the CuO_2 planes in deforming the Fermi surface in the underdoped regime (Yamase et al., 2021).

Positron annihilation

The electron momentum distribution can also be probed using positrons. In this case, it is the electron momentum distribution *as seen by* the positron which is measured, and it is often called the electron-positron momentum distribution or the ‘two-photon momentum distribution’ (TPMD, where the ‘two-photon’ refers to the pair of annihilation γ -photons which are experimentally measured).

Within the independent particle model (in which the electron and positron are treated as non-interacting independent particles), the TPMD can be expressed as

$$\rho^{2\gamma}(\mathbf{p}) = \sum_{\text{occ}} \left(\frac{1}{2\pi\hbar} \right)^3 \left| \int \psi(\mathbf{r}) \psi_+^*(\mathbf{r}) \exp(-i\mathbf{p} \cdot \mathbf{r}/\hbar) d\mathbf{r} \right|^2, \quad (14)$$

where $\psi_+^*(\mathbf{r})$ represents the (complex conjugate of the) positron wavefunction.

The technique is commonly known as 2D angular correlation of annihilation radiation (2D-ACAR). Positrons, usually obtained from a ^{22}Na source, are implanted into the sample being studied. The positrons have a typical β energy spectrum with a maximum energy of about 0.5 MeV, and thus penetrate into the bulk of the sample. Typical source activity and annihilation rates mean that there will only ever be one positron in the sample at any time. After thermalization, which happens on a timescale of several picoseconds in a metal (Kubica and Stewart, 1975), the positron will propagate in its own Bloch state (at the bottom of its own positronic band) for ~ 100 ps before annihilation with an electron which proceeds predominantly through the creation of two

Fig. 15 Geometry of a 2D-ACAR experiment. A pair of γ photons resulting from electron-positron annihilation are detected in coincidence on a pair of position-sensitive detectors. The angular deviation from being back-to-back can then be calculated from the positions ΔX and ΔY on the two detectors.

γ -photons which, owing to conservation of energy and momentum will be emitted back-to-back in the center-of-momentum frame. However, in the laboratory frame, in which the electron and positron have a finite momentum, there will be a small angle ($\sim \text{mrad}$) between the γ s.

Since the positron has only a thermal momentum, the combined momentum of the pair is completely dominated by that of the electron. Two components of the momentum can be directly inferred by measuring the angular deviation of the two γ from being back-to-back by recording where they hit position-sensitive detectors (Dugdale et al., 2013) typically located about 10 m away on either side of the sample, as shown in Fig. 15.

If the momentum of the pair has components (p_x, p_y, p_z) , then

$$p_x \approx mc\theta_x, \quad (15)$$

and

$$p_y \approx mc\theta_y, \quad (16)$$

where m is the electron rest mass, c is the speed of light and θ_x and θ_y can be calculated from the detected γ positions if the distance of each detector from the sample is L .

$$\theta_x = \frac{\Delta x_1 + \Delta x_2}{L}, \quad (17)$$

and

$$\theta_y = \frac{\Delta y_1 + \Delta y_2}{L}. \quad (18)$$

The remaining momentum component, which would be encoded in a Doppler shift in the energy of the photons, cannot be measured with the same precision. This means that this third component is integrated over, and the resulting spectrum is a projection of the underlying momentum distribution. Tomographic reconstruction is necessary to regain the third momentum component, and this is achieved by measuring down a small number (typically fewer than six) crystallographic directions. However, in many cases, an excellent understanding of the Fermi surface topology can be gained from a single high-symmetry projection. The momentum resolution is normally dominated (at least at low temperatures) by the precision with which the coordinates of γ -photons can be recorded on the two position-sensitive detectors as well as uncertainty in the origin of annihilation due to the source spot on the sample. The latest generation of detectors offer sub-mm position resolutions Dugdale et al. (2013), which at typical distances from the sample means momentum resolutions of a few percent of the Brillouin zone of Cu.

Not all electrons are *seen* by the positron equally, since the positron's positive charge means that it is strongly repelled by the nucleus. This results in a smaller overlap between the positron's wavefunction and those of the most tightly bound electrons. Their contribution is therefore strongly suppressed, but that from electrons at the Fermi surface is enhanced since annihilation is more likely to occur with one from among the screening cloud of electrons at the Fermi surface. While many-body electron-positron correlations can modulate the shape of the momentum density, the position of the discontinuity is not affected (Majumdar, 1965) meaning that the Fermi surface can be clearly identified. Although the TPMD is sensitive to electron-positron correlations (for example, see Laverock et al. (2010)), it is still possible to study the effect of electron correlation on the occupation numbers in k -space (Harris-Lee et al., 2021). Positron annihilation experiments have been used to investigate the impact of electron correlation on the Fermi surface of vanadium (Weber et al., 2017). This was achieved by comparing the densities calculated using a combination of DFT and dynamical mean-field theory with experimental measurements.

Spin-resolved measurements

Both Compton scattering and positron annihilation can be operated in a spin-resolved mode. In the case of Compton scattering, magnetic measurements exploit the spin-dependent term in the scattering cross-section for circularly polarized photons (Duffy, 2013). Magnetic Compton scattering experiments are typically performed using a solid-state detector which has a relatively poor energy resolution corresponding to a momentum resolution which is comparable to the size of the Brillouin zone, making any sensible study of the Fermi surface impossible. However, high-resolution magnetic Compton profiles with a resolution acceptable for Fermi surface studies have been measured (Sakurai et al., 1994). Spin-resolved positron annihilation relies on the parity violation in beta decay which manifests as a preferential positron spin parallel to its velocity vector. It is possible to extract a spin-resolved Fermi surface (Hanssen et al., 1990; Weber et al., 2015) by making measurements with a magnetic field in different directions, since two-photon annihilation relies on the electron and positron having opposite spins.

Strengths and weaknesses of the various techniques

There is a great deal of complementarity between the techniques which have been discussed. All have their advantages and disadvantages, their strengths and weaknesses.

Sensitivity to correlations

Through their ability to measure the effective mass, quantum oscillations can probe electron correlation on the low energy (<0.1 meV) scale. ARPES can provide complementary information about correlation through the self-energy, for example, directly imaging the renormalization of the bandwidth and revealing the presence of Hubbard bands. Since these are on a larger energy scale (~ 1 eV), these two techniques provide complementary information. AMROs, however, are insensitive to many-body correlations. Both positron annihilation and Compton scattering are sensitive probes of electron correlation.

Sample purity

To observe quantum oscillations and AMROs, high-quality crystals with low residual resistivities are required to give a high relaxation time, τ , such that $\omega_c \tau \gg 1$. For bulk-representative measurements, ARPES requires clean, ordered surfaces. While positron annihilation does not require purity, it is the concentration of open-volume defects (such as vacancies) which is important as positrons will be trapped resulting in isotropic momentum distributions. Vacancy concentrations as low as one part-per-million can be enough to trap every positron. Compton scattering is insensitive to both the purity of the sample or vacancies.

Temperature

To observe quantum oscillations, the condition $k_B T < \hbar \omega_c$ must be satisfied which implies both large magnetic fields and low temperatures (often in the mK regime requiring ^3He cryostats or dilution refrigerators). For AMROs, oscillations are observable until the scattering due to temperature reduces the relaxation time such that $\omega_c \tau \gg 1$ is no longer satisfied, also restricting the technique to low temperatures. ARPES can be carried out at elevated temperatures, but resolution will be degraded. Both Compton scattering and positron annihilation can be carried out at elevated temperatures, but for positron annihilation increased temperature degrades the resolution since the thermal energy of the positron contributes to the overall momentum resolution.

Dimensionality

Quantum oscillations, positron annihilation and Compton scattering are all capable of delivering full three-dimensional Fermi surface geometries, but the latter two do require tomographic resolution. Although ARPES is well-suited to 2D materials, it can also provide three-dimensional Fermi surface information. AMROs are only observable in quasi-1D and quasi-2D materials.

k -space resolution

In the following discussion, the resolution is compared to the size of the Brillouin zone of Cu (for lattice constant a , Brillouin zone size of a real-space face-centered cubic lattice is $4\pi/a = 3.47 \text{ \AA}^{-1}$). The k -space resolution of quantum oscillations is excellent, reaching up to 10 ppm of the Brillouin zone in the most favorable situations, although a typical experiment with a carefully calibrated magnetic field might deliver a precision of 0.1% of the Brillouin zone (Bergemann, 2005). ARPES experiments operate typically at the level of 1% of that Brillouin zone. A similar resolution can be achieved in AMRO experiments (where the resolution crucially depends on the number of oscillations which can be observed), with $\sim 1\%$ being possible for Yamaji oscillations in a good crystal (Bergemann, 2005). Positron annihilation experiments can routinely achieve a resolution of about 4% of the Brillouin zone, and Compton scattering is typically about 5%.

Bulk sensitivity

Quantum oscillations, AMROs, positron annihilation and Compton scattering all probe the bulk electronic structure. ARPES is sensitive to the surface, but different degrees of bulk sensitivity can be achieved by varying the photon energy.

Other techniques

There are several other techniques, some of which have played an important role in the history of Fermi surface determination. Some of these are discussed below.

Anomalous skin effect

A high-frequency (radio frequency) field will induce currents to flow in the surface of a metal, preventing the field penetrating into the bulk. However, the depth of the penetration, known as the 'skin depth', depends on the (frequency dependent) electrical conductivity of the metal. At very high frequencies, for a pure specimen at low temperature (such that the conductivity is very high), the skin depth can be less than the electron mean-free-path. In such a case, only electrons which are travelling parallel to the surface (and thus stay within the skin layer) can interact significantly with the field. The consequence of this is a so-called 'anomalous skin depth' which depends on the ratio of the conductivity to the mean-free-path (Ziman, 1962). For a free-electron metal, this ratio is a constant which depends on the velocity of the electrons on the Fermi surface, and not on any scattering mechanism. Since only electrons parallel to the surface contribute, if the Fermi surface is not a sphere then samples with cut surfaces in different orientations should behave differently. A detailed analysis shows that measurements of the surface impedance can provide information about the radius of curvature of the Fermi surface in a plane normal to the sample surface and parallel to the direction in which the impedance is being measured. Through measurements of the anomalous skin effect Pippard was able to demonstrate that the Fermi surface of Cu was very distorted, and that it most likely touched the boundary of the Brillouin zone (Pippard, 1957).

Cyclotron resonance

In the Azbel'-Kaner geometry (Azbel' and Kaner, 1958), the magnetic field is aligned exactly parallel to the surface of the metal such that the electrons will execute helical paths in planes perpendicular to the field. If the sample is exposed to a microwave electromagnetic field, although most of the electron's helical path will be below the skin depth (and thus preserved from the microwave field), during the part of the path which is within the skin depth, the electron will be able to interact with, and rapidly absorb energy from the field. Resonances will therefore occur when the microwave frequency coincides with the cyclotron frequency (or its harmonics). In an experiment, the microwave frequency is fixed while the magnetic field is increased, leading to a series of peaks in the measured signal (the derivative of the surface resistance with respect to magnetic field) equally spaced in inverse magnetic field. As in the quantum oscillatory experiments, the signal will be dominated by extremal orbits on the Fermi surface. It should be emphasized that this does not deliver the geometry of the Fermi surface, but rather the *dynamical* cyclotron mass which, to first order, is only renormalized by electron-phonon interactions. This means that when combined with a quantum oscillations measurement, electron-phonon effects can be separated from those of electron-electron correlation (Singleton et al., 1992). However, as well as being able to compare these masses with theoretical predictions, the measured cyclotron frequencies deliver the derivatives of the band structure in *k*-space (Ziman, 1962).

Kohn anomalies, RKKY and Friedel oscillations

The wavevector-dependent screening properties of the electrons in a metal are governed by the shape of the Fermi surface (Dugdale, 2016). Kohn suggested that singularities arising from the geometry of the Fermi surface could manifest themselves in phonon spectra (Kohn, 1959), pointing out that the shape of the Fermi surface could be inferred from the locations of singularities in the vibrational spectra. These 'images of the Fermi surface' (as they were described) in the phonon spectra of Pb were measured soon afterwards (Woll and Kohn, 1962; Brockhouse et al., 1962). The electron-phonon coupling is particularly strong in Pb; in practice these anomalies are quite weak for most metals. However, the idea of mapping out the Fermi surface from these Kohn anomalies was subsequently explored in Al (Weymouth and Stedman, 1970). The conclusion, however, was that in general any sensible interpretation on a hitherto unknown Fermi surface would rely heavily on additional information and would at best be a complementary Fermi surface probe. More recently, the thermal diffuse scattering of x-rays has been used to image the Fermi surface of Zn (Bosak et al., 2009). By combining their measurements with both an inelastic X-ray scattering study and *ab initio* DFT calculations, they were able to show that diffuse scattering is connected to the phonons, and that an image of the Fermi surface can be obtained owing to the electron-phonon coupling.

A similar case could be made about exploiting the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction to understand the Fermi surface (Roth et al., 1966). And just as the RKKY interaction concerns the screening of spins, Friedel oscillations arise from the screening of charge impurities (Friedel, 1958). The Fermi surface of a Cu (111) surface (that is, the *surface* Fermi surface, as opposed to the bulk) is a circle of radius $k_F = 0.215 \text{ \AA}^{-1}$ (Winkelmann et al., 2012). Oscillations with a spatial period of π/k_F or $\approx 15 \text{ \AA}$, have

been observed around point defects on a Cu (111) surface in scanning-tunneling microscope (STM) images (Crommie et al., 1993). Fourier transforms of such ‘quantum interference’ can provide images of the Fermi surface. An insightful comparison of the Fermi surfaces of Sr_2RhO_4 obtained from ARPES, STM and quantum oscillations can be found in Battisti et al. (2020).

Conclusion

For as long as the technological exploitation of new metallic materials depends on understanding their electronic structure, determining the topologies of their Fermi surface will continue to be vital. Progress continues to be made through the ingenuity of new tools and improvements in the precision and efficiency of more established ones. Fermi surface measurements continue to demand approaches which challenge our expertise in harnessing large magnetic fields, ultra-low temperatures and high pressures, which take advantage of large-scale national and international scientific facilities, which push our theoretical and computational abilities to new limits. And the excitement of contributing to the solution of some of the biggest problems in physicists awaits a new generation of Fermiologists.

Acknowledgments

I am indebted to Jude Laverock for many years of sage advice. And to my Dad, for sparking and nurturing my passion for physics.

Abstract

After the inception of quantum mechanics, workers recognized that an exact solution for electronic structure of interacting atoms was intractable. Over the past century, this situation has prompted a search for *practical methods* to accurately approximate atomic systems. One of the most successful practical methods centers on the creation of *pseudopotentials*, which only reproduce the chemically active states. Since the energy and length scales are set by the valence states, these potentials dramatically simplify the problem. We outline the construction of pseudopotentials with some example applications to condensed matter systems.

Introduction

A long sought goal of condensed matter physics centers on the ability to predict the properties of materials solely based on the atomic species present. Before the turn of the twentieth century, such a goal was not in the realm of possibility. Quantum mechanics had not been invented, much less applied to materials. Moreover, as the rudimentary quantum theory evolved, e.g., the Bohr theory of the hydrogen atom, the arguments at the time were often focused on the structure of an individual atom. Workers did not dream of addressing problems of materials containing a large number of atoms. However, as quantum mechanics became accepted for atoms, interest in applying quantum theory to materials grew.

Indeed, once the predictive power of quantum mechanics for atoms and simple molecules became clear, the notion of predicting materials properties by solving the quantum mechanical behavior of the system of interest, did not seem so outlandish. One of the first visionaries was P.A.M. Dirac (Dirac, 1929). In 1930 he stated: *The underlying physical laws necessary for the mathematical theory of a large part of physics and the whole of chemistry are thus completely known, and the difficulty is only that the exact application of these laws leads to equations much too complicated to be soluble. It therefore becomes desirable that approximate practical methods of applying quantum mechanics should be developed, which can lead to an explanation of the main features of complex atomic systems without too much computation.*

The implication of this statement was clear. A solution of the quantum mechanical problem would yield the “whole of chemistry.” One could predict properties of the chemical bond and the corresponding materials properties of matter without resort to laboratory work. Chemistry and materials properties could be predicted by computation. However, the equations in question were much too complicated to be solved when Dirac made this statement. In fact, they are much too complicated to be solved today, even with state of the art computational platforms.

As Dirac anticipated, the key to progress in this area is to develop “approximate practical methods.” Today, we have a number of such practical methods that allow us to access some properties in a manner Dirac suggested. The first successes appeared some 30 or 40 years after Dirac’s statement and were led by the development of the *pseudopotential* concept.

The pseudopotential model of a solid provided a practical model to address the quantum mechanical problem and advances in computers provided the means to overcome numerical hurdles.

One notable attribute of a pseudopotential is that it allows one to address directly chemically active valence states of an atom and remove from consideration inert core states. This decomposition between active and inactive states is readily done for most atoms, e.g., in a silicon atom the $1s^2 2s^2 2p^6$ core states are tightly bound compared to the $3s^2 3p^2$ valence states. The physical nature of this decomposition is confirmed by the content of the periodic table in which chemical properties are grouped into columns of elements with similar valence electron configurations.

In Fig. 1, we illustrate the pseudopotential model for a crystalline solid. In this case, the core electrons and nucleus of an atom are treated as an inert, transferable ion core; the valence electrons are treated as an electron sea moving under the influence of the ion cores.

[☆]Change History: October 2022. JR Chelikowsky updated the chapter.

Fig. 1 Pseudopotential model of a crystal. The nucleus and core electrons form a chemically inert ion core, which can be replaced by a pseudopotential.

This pseudopotential picture sets the *length and energy* scale to the problem that is determined by the valence states. Consider a heavy metal atom like Pb. When compared to the outermost electrons, the energies of the innermost electron states are a factor of $\sim 10^4$ more tightly bound. The length scale of these states are also highly localized when compared to the valence states, typically by a factor of $\sim 10^2$. Without the pseudopotential approximation, any description of the electronic states in Pb would need to span orders of magnitude differences in energy and length scales.

Early pseudopotentials

The pseudopotential idea is not new. Several key elements were identified after the advent of quantum mechanics. Both Enrico Fermi and Hans Hellmann contributed seminal papers in the mid-1930s (Fermi, 1934; Hellman, 1935). Interestingly, they recognized somewhat different, but important elements of pseudopotential theory. Fermi's turned his focus on determining the phase shift in wave functions of high lying alkali atoms subject to perturbations from foreign atoms. He correctly argued that if one were interested in the long range behavior of the wave function, it was not necessary to get the details correct near the nucleus. It should be possible to replace the true potential near the nucleus with a simple potential, or pseudopotential, that yields a similar value for the long range part. Fermi also established the importance of a scattering length within this paper.

Hellmann's work is probably closer to our contemporary picture (Schwarz et al., 1999a,b). Hellmann recognized that the valence orbitals for many electron atoms contained pronounced oscillations, a *nodal structure*, within the atomic core. Determining an accurate description of the oscillating behavior near the core and the long range behavior in the chemical relevant region would render the problem computationally difficult. Hellmann also observed that these core electron did not play an important role in determining the chemical bond.

Today, we would argue that the valence electrons experience an additional kinetic energy contribution in the core region because of the orthogonality requirement, i.e., the valence state of an atom is orthogonal to a core state by nodal structure in the core region. In his 1935 paper, Hellmann proposed that this kinetic energy term could be quantified using the Thomas-Fermi expression for the kinetic energy of a free electron gas, which depends only on the electron density (Hellman, 1935). When this term was added to the attractive Coulomb part of the valence electron interacting with the ion core, he argued that the resulting potential was "weak and constant." An example of a pseudopotential similar to those Hellmann suggested is schematically illustrated in Fig. 2.

The Phillips-Kleinman cancellation theorem

While the work of Hellmann and Fermi established the elementary ideas associated with pseudopotentials, a rigorous transcription of an "all electron" potential to a pseudopotential was lacking. One of the earliest transcriptions is based on the ideas of Phillips and Kleinman (Phillips and Kleinman, 1959; Kleinman and Phillips, 1960a,b; Phillips and Kleinman, 1962). Although their

Fig. 2 Schematic of an ion core pseudopotential. The “all electron” potential and the pseudopotential ion core potential are similar outside of the core region.

conclusions are more far reaching, we will focus on solving the electronic structure problem for an isolated atom. We will make the “one-electron” approximation, i.e., the Schrödinger equation for the atomic orbitals can be written as

$$H\Psi_n(\vec{r}) = \left[\frac{-\hbar^2 \nabla^2}{2m} + V(\vec{r}) \right] \Psi_n(\vec{r}) = E_n \Psi_n(\vec{r}), \quad (1)$$

where m is the electron mass, $\hbar$ is Planck’s constant divided by 2π , V is the all electron potential and (E_n, Ψ_n) are the eigen pairs: the energy levels and corresponding wave functions. Here we assume both core and valence states exist. We express the wave function for the valence state, Ψ_v , as

$$\Psi_v(\vec{r}) = \Phi_v^p(\vec{r}) + \sum_c a_{v,c} \Psi_c(\vec{r}). \quad (2)$$

The sum is over the core states, Ψ_c , and Φ_v^p represents the pseudopotential wave function. This form of the wave function recognizes that near the nucleus the valence wave function should appear atomic like. Away from the nucleus, we expect: $\Psi_v(\vec{r}) \approx \Phi_v^p(\vec{r})$. Moreover, we expect $\Phi_v^p(\vec{r})$ outside of the core region to be nodeless and slowly varying.

To determine the admixture of the core state with the pseudo wave function, we demand the following condition

$$\int \Psi_c^*(\vec{r}) \Psi_v(\vec{r}) d^3r = \langle \Psi_c | \Psi_v \rangle = 0, \quad (3)$$

where we use the “bra-ket” notation. The valence state must be orthogonal to the core state, owing to the nature of the eigenvalue problem. The orthogonality requirement yields

$$a_{v,c} = - \langle \Psi_c | \Phi_v^p \rangle. \quad (4)$$

This form of the wave function was first proposed by Conyers Herring (Herring, 1940) in a different context. Herring proposed describing electronic states in crystals using “orthogonalized plane waves.” In this model, the valence states in a solid were replicated using plane waves that were orthogonalized to the core levels.

If we apply the Hamiltonian in Eq. (1) to the valence wave function, we obtain

$$H\Phi_v^p + \sum_c \langle \Psi_c | \Phi_v^p \rangle (E_v - E_c) \Psi_c = E_v \Phi_v^p. \quad (5)$$

We have used $H\Psi_c = E_c\Psi_c$. We can define a pseudopotential Hamiltonian, H^p , as

$$H^p = H + \mathcal{V}_R, \quad (6)$$

where we define a potential operator, $\mathcal{V}_R$, as

$$\mathcal{V}_R = \sum_c \langle \Psi_c | \dots \rangle (E_v - E_c) \Psi_c. \quad (7)$$

The empty “ket” given by $|\dots\rangle$ requires an operation wherein the wave function is projected on Ψ_c and the functional dependence now corresponds to Ψ_c . If we define a pseudopotential as $V_p = V + V_R$ we now have now transformed the one-electron Schrödinger equation to

$$H_p \Phi_v^p = \left[\frac{-\hbar^2 \nabla^2}{2m} + V_p \right] \Phi_v^p = E_v \Phi_v^p. \quad (8)$$

This description of an atom has a number of advantages. The repulsive part of the potential, V_R , largely cancels the attractive part of the all electron potential in the core region. The pseudo wave function is smooth as the core oscillations have been removed and the eigenvalue, E_v , is identical to the all electron potential. While the wave function is now amenable to a simple basis, the pseudopotential within this construction is more complex than the all electron potential. The potential is weak and only binds the valence state, but it is also energy dependent, state dependent and involves a nonlocal, non-Hermitian operator. Owing to these complexities, the Phillips-Kleinman potential is rarely, if ever, used for calculating pseudopotentials. However, the cancellation theorem is useful in demonstrating the essential features of a pseudopotential.

Model potentials

For many purposes, a model pseudopotential can be used to capture the essential physics and advance the essential understanding of the system of interest. As a starting point, we consider a simple model for the ion-core pseudopotential. This potential is expected to be transferable since it depends only on the nuclear and core states. In a vein similar to what Hellmann proposed, we write

$$V_c^p(r) = \begin{cases} 0 & r \leq r_c, \\ -Z_v e^2 / r & r > r_c. \end{cases} \quad (9)$$

Within the core, this potential is defined as an “empty core.” r_c defines the size of the core region of the potential. The electron charge is e , and Z_v is the number of valence electrons.

In most cases, the number of valence electrons is simply given by the column of the periodic table. Some issues arise in the presence of loosely bound core states. An example is the $3d$ state in Cu, which can be taken as a valence state or a core state. This issue can be tested by considering both cases and assessing any differences.

To form a solution for the electronic structure of a crystal, we need to input the structure of the crystal and account for the interactions of the valence electrons. This is often handled by expressing the wave functions in terms of a plane wave basis, which requires an expression of the potential in Fourier-space characterized by an atomic form factor, $V_c^p(q)$

$$V_c^p(q) = \frac{1}{\Omega_a} \int V_c^p(r) \exp(i \vec{q} \cdot \vec{r}) d^3r. \quad (10)$$

where Ω_a is the atomic volume. The atomic form factor for empty core pseudopotential is given by

$$V_c^p(q) = \frac{-4\pi Z_v e^2}{\Omega_a q^2} \cos(qr_c). \quad (11)$$

The long range nature of the Coulomb tail requires special handling in executing this integral when $q \rightarrow 0$. Also, the form factor “rings”, i.e., the form factor oscillators as a cosine function owing to the discontinuity in the potential at r_c .

The ion core pseudopotential needs to be screened by the valence electrons. For simplicity, Thomas-Fermi screening is often used for this purpose (Kittel, 2005)

$$V_a^p(q) = \frac{V_c^p(q)}{\epsilon_{TF}(q)}, \quad (12)$$

where the screening is characterized by a dielectric function given by

$$\epsilon_{TF}(q) = 1 + \frac{K_s^2}{q^2}, \quad (13)$$

where $1/K_s$ is the Thomas-Fermi screening length $K_s^2 = 6\pi n e^2 / E_F$, which depends on the valence electron density, ($n = Z_v / \Omega_a$) and E_F is the Fermi energy for a free electron gas of density, n . The atomic form factor is now given by

$$V_a^p(q) = \frac{-4\pi e^2 n}{q^2 + K_s^2} \cos(qr_c). \quad (14)$$

A common practice is to set the potential to zero outside of the second node to remove the oscillatory or ringing behavior of the $\cos(qr_c)$ term. This simple potential is characterize by only one parameter, r_c and the electron density, n .

An interesting consequence of Thomas-Fermi screening is that the potential now has a well defined value when $q = 0$,

Fig. 3 Model of an atomic pseudopotential. The required form factors can be extracted from this model. Note the limiting case of $G = 0$ for a metallic system.

$$V_a^p(0) = \frac{-4\pi e^2 n}{K_s^2} = -\frac{2}{3} E_F. \quad (15)$$

The $q = 0$ term corresponds to the average of the crystalline potential. This limiting case from Thomas-Fermi screening is not a very good approximation for a semiconductor like silicon and is more appropriate for a metal. This is expected as the Thomas-Fermi expression works best for a “free electron” gas, which is likely to be a better model for a simple metal as opposed to a semiconductor.

We have considered a general value, q , in Fourier space, but symmetry restricts the value of q to be a reciprocal space vector, determined by the crystal lattice (Kittel, 2005). This is depicted in Fig. 3 where a schematic of a screened atomic potential is illustrated.

We can write the total crystalline potential as

$$V^p(\vec{r}) = \sum_{\vec{R}, \vec{\tau}} V_a^p(\vec{r} - \vec{R} - \vec{\tau}), \quad (16)$$

where the position of the lattice point are given by the lattice vector, $\vec{R}$, and the atomic positions associated with the lattice point by the basis vector, $\vec{\tau}$. Using the atomic form factors, we can express this pseudopotential as

$$V^p(\vec{r}) = \sum_{\vec{G}, \vec{\tau}} V_a^p(G) S(\vec{G}) \exp(i\vec{G} \cdot \vec{r}), \quad (17)$$

where $S(\vec{G})$ is the structure factor:

$$S(\vec{G}) = \frac{1}{N_a} \sum_{\vec{\tau}} \exp(i\vec{G} \cdot \vec{\tau}). \quad (18)$$

$\vec{G}$ is a reciprocal lattice vector and N_a is the number of atoms in the unit cell (Kittel, 2005). This expression assumes an elemental crystal, but generalizing the potential to a crystal with different atomic species present is straightforward. The total pseudopotential is determined by the atomic structure factor, which represents the screened ion core potential, and the crystal structure determined by the reciprocal lattice and the atomic positions.

This simple pseudopotential is called a “local” pseudopotential as the ion core is a simple function of position. The potential does not reflect elements present in the Phillips-Kleinman cancellation theorem wherein the potential depends on the nature of the core states. For example, in carbon there is no $1p$ core state and the valence $2p$ is not required to be orthogonal to the core. This is not true for silicon in which both s and p states exist in the core, both the s and p valence states experience a repulsive term. Historically, this difference has been used to explain why silicon and carbon chemistry are different, the former representing “geology” and the later “biology” (Kittel, 2005).

The empty core model potential can be modified to reflect the state dependence

$$V_{c,l}^p(r) = \begin{cases} A_l & r \leq r_{c,l} \\ -Z_v e^2 / r & r > r_{c,l} \end{cases} \quad (19)$$

This potential is not a simple function of position, but rather acts on the l -component present in the wave function (Cohen and Chelikowsky, 1982, 1989; Chelikowsky and Cohen, 1992). This can be accomplished by using a projection operator as will be discussed later. There are additional parameters to be determined as the well depth and size must be fixed for each l -component.

A common practice in the early days of pseudopotential involved estimating the well depths and sizes (A_l , $r_{c,l}$) to replicate optical data of ionized atoms. For example, to construct an ion core pseudopotential for an Al atom, one needs to consider the optical excitations for an Al^{+2} ion. In some cases, this is relatively easy, e.g., treating the Na atom does not involve an ionized atom.

However, determining such parameters for an O atom requires the examination of an O^{+5} ion. The experimental task of multiply ionizing atoms and measuring the resulting atomic levels is difficult. Often the potentials were estimated by extrapolation from lighter atoms to heavier ones. Another issue concerns using more accurate dielectric functions screening the potentials. Both issues were the subject of a number of studies. By the mid 1960s an inventory of such model potentials existed (Animalu and Heine, 1965; Cohen and Heine, 1970) with some success.

The empirical pseudopotential method

One of the most significant advances in applying pseudopotential theory was the development of the empirical pseudopotential method (EPM). The intuitive picture of Fermi and Hellmann was greatly advanced by Phillips and Kleinman; however, a practical method of predicting accurate energy band structures was not achieved until the EPM. This method developed in the late 1960s was based on fixing an energy band so that a measured response function, such as the reflectivity of a solid, was reproduced (Cohen and Bergstresser, 1965). To accomplish this feat, one had to develop a framework of translating an energy band solution to a response function.

Determining the energy band structure for a simple pseudopotential is not difficult. If we are given the crystalline potential, we can solve the corresponding eigenvalue problem (Eq. 1) using a variety of approaches. Since the pseudopotential is weak compared to the all electron potential, we can write the wave function in terms of a plane wave basis, which are expected to converge quickly

$$\psi_{n,\vec{k}}(\vec{r}) = \sum_{\vec{G}} \alpha_n(\vec{k}, \vec{G}) \exp(i(\vec{k} + \vec{G}) \cdot \vec{r}). \quad (20)$$

n is a band index, $\vec{k}$ is the wave vector. The sum is over all reciprocal lattice vectors, $\{\vec{G}\}$, but in principle the sum is truncated for $|\vec{k} + \vec{G}| > G_{max}$. This form of the wave function is consistent with the Bloch form of the wave function for a periodic potential. The Bloch form of the wave function allows one to express the corresponding periodicity of the wave function, save a phase factor determined by the wave vector

$$\psi_{n,\vec{k}}(\vec{r} + \vec{R}) = \exp(i\vec{k} \cdot \vec{R}) \psi_{n,\vec{k}}(\vec{r}). \quad (21)$$

Inserting the crystalline potential (Eq. 17) and the plane wave basis (Eq. 20) in the one-electron Schrödinger equation, yields the following:

$$\sum_{\vec{G}'} \left\{ \left[\frac{\hbar^2}{2m} (\vec{k} + \vec{G})^2 - E_n(\vec{k}) \right] \delta_{\vec{G}\vec{G}'} + V_a^p(|\vec{G}' - \vec{G}|) S(|\vec{G}' - \vec{G}|) \right\} \alpha_n(\vec{k}, \vec{G}') = 0, \quad (22)$$

which corresponds to a set of linear equations, one for each $\vec{G}$ -vector in the set. For a non-trivial solution, we require the following:

$$\det \left| \left[\frac{\hbar^2}{2m} (\vec{k} + \vec{G})^2 - E_n(\vec{k}) \right] \delta_{\vec{G}\vec{G}'} + V_a^p(|\vec{G}' - \vec{G}|) S(|\vec{G}' - \vec{G}|) \right| = 0, \quad (23)$$

The diagonal elements of this determinant contain the kinetic energy contribution; the off diagonal elements contain the form factors for the pseudopotential and the structure factor. This is an eigenvalue problem and a standard mathematical problem, which is easily handled, save for large systems, i.e., the matrix is large and dense (Saad et al., 2010). Owing to the rapid convergence of the pseudopotentials in Fourier space for common semiconductors or simple metals, one needs only a few hundred plane waves to obtain a converged result.

As a specific example, consider the energy band structure of germanium as computed by pseudopotentials. The band structure is shown in Fig. 4. The energy at point $\vec{k}$ and band n , $E_n(\vec{k})$, is plotted along different high symmetry directions, e.g., the energy band along Γ to X is plotted from $\vec{k} = (2\pi/a)(0, 0, 0)$ to $\vec{k} = (2\pi/a)(1, 0, 0)$ along the $\langle 100 \rangle$ or Δ direction. The input required to compute the energy band includes the crystal structure of germanium, which occurs in a diamond structure, and the form factors required to construct the pseudopotential for the crystal.

As indicated in Fig. 3, only three form factors are required for this case. The empirical pseudopotential method treats these form factors as adjustable parameters. The form factors are not linearly independent, so the information required to fix the form factors is not great. Three or four band structure features are sufficient. As a starting point, one can use a model pseudopotential based on optical spectra for atoms. The form factors are then refined by using optical or photoemission data for the crystal of interest.

Given the energy band of a crystal, one can compute the complex index of refraction and the reflectivity. The first such computations were based on simplified dielectric theories that excluded electron-hole interactions (Cohen and Chelikowsky, 1989). Four ingredients are included: conservation of energy, conservation of crystal momentum, wave function symmetry and the number of states accessible. Energy conservation requires a photon energy sufficient to excite an electron from an occupied

Fig. 4 Band structure of germanium using pseudopotentials (Cohen and Chelikowsky, 1989). The valence band maximum is set to zero.

valence band to an empty conduction band. Such transitions are direct, i.e., the wave vector of the valence band and conduction bands are the same so that crystal momentum is conserved. Just as in an atomic state, the overlap of initial and final states should have a dipole component to couple to the electric field of the photon. Finally, for a given energy difference and wave vector, one can compute the number of possible valence and conduction band states accessible. The larger the number of states, the more probable is an optical excitation.

The computed reflectivity of germanium is given in Fig. 5. The agreement between experiment and theory is sufficient to identify features in the reflectivity spectrum that can be associated with energy band features. For example, the reflectivity peak around 2 eV can be identified with transitions occurring between the top of the valence band and lowest conduction bands near the L -high symmetry point. If the theoretical reflectivity for this part of the spectrum does not agree with experiment, we know that the energy band structure is incorrect. If the theoretical reflectivity agrees with experiment, we can be reasonably confident that the energy band structure is correct.

Fig. 5 Experimental (Philipp and Ehrenreich, 1963) and theoretical reflectivity of crystalline germanium (Cohen and Chelikowsky, 1989).

The empirical pseudopotential method provided the first realistic energy band structures for many simple metals and semiconductors (Cohen and Chelikowsky, 1989). Most of our knowledge of the electronic structure of these materials was pioneered by this type of pseudopotential.

However, the empirical pseudopotential method is somewhat limited for several reasons. The potential requires experimental input and this input can bias the pseudopotential. For example, suppose we fit the optical properties of GaSb and extract a Ga potential, we must be careful in trying to use this fit Ga potential in a different crystal. This potential might work fine in GaAs, which has a similar bonding configuration when compared to GaSb, but the potential may fail to describe GaN, which is considerably more ionic than GaSb.

A related problem concerns how the form factors are fit. For high symmetry systems, only a small subset of reciprocal lattice vectors come into play. If the crystal volume or structure changes, one must extrapolate to a new subset of vectors. The required set of data may notably exceed the available experimental data. This problem can occur at a surface or at a defect. In crystalline GaAs, each Ga atom is surrounded by four As atoms. For the cleavage plane, the (110) surface, the Ga atom is bonded to three As atoms. Given the coordination change, the surface Ga atom cannot be expected to retain a "bulk-like" screening potential. There is no reason to be confident that the Ga pseudopotential extracted from the crystalline environment will be very accurate at the surface. Of course, this problem is made worse if one wants to examine a material where the structure is not known as for an amorphous solid or a structure varying in time such as in a liquid state, where the coordination around an atom may continuously change.

First principles pseudopotentials using density-functional theory

A key issue is how to account for the valence charge density screening the ion core pseudopotential. We can consider the form factors to be composed of two interactions: the "ion core-valence electron" interaction and the "valence electron-valence electron" interaction. A fundamental postulate of the pseudopotential method is that the ion core pseudopotential is not dependent on the chemical environment. We assume that this part of the potential can be transferred from one environment to another with no loss in accuracy. A notable problem is the determination of the total pseudopotential by including interactions between the valence electrons. We illustrated the use of Thomas-Fermi dielectric screening in model potentials, which can be used as a first pass for empirical potentials.

A better approach constructs a self-consistent potential by using the valence charge density within density functional theory. Let us assume a one-electron Hamiltonian, which can be based on density functional theory (Hohenberg and Kohn, 1964; Kohn and Sham, 1965)

$$\left[\frac{-\hbar^2 \nabla^2}{2m} + V_{ion}^p(\vec{r}) + V_H(\vec{r}) + V_{xc}(\vec{r}) \right] \Psi_n(\vec{r}) = E_n \Psi_n(\vec{r}). \quad (24)$$

The ion-core pseudopotential, V_{ion}^p , can be taken as a linear superposition of ion core atomic potentials. Determining the ionic potential can be accomplished by resort to atomic structure calculations. The potential arising from the valence-electron interactions can be divided into two parts. One part represents the "classical" electrostatic terms, named the Hartree or Coulomb potential

$$\begin{aligned} \nabla^2 V_H(\vec{r}) &= -4\pi e \rho(\vec{r}), \\ \rho(\vec{r}) &= e \sum_{n, \text{occup}} |\Psi_n(\vec{r})|^2. \end{aligned} \quad (25)$$

Fig. 6 Self-consistent field loop. The loop is repeated until the “input” and “output” charge densities are equal to within some specified tolerance.

where ρ is the valence electron charge density. The second part of the screening potential, the effective “exchange-correlation” part of the potential, V_{xc} , is quantum mechanical in nature.

A common approximation for this part of the potential is the local density approximation. The potential depends only on the charge density at the point of interest, $V_{xc}(\vec{r}) = V_{xc}[\rho(\vec{r})]$. In principle, density functional theory is exact, provided one can obtain an exact functional for V_{xc} . One productive approach is to assume that the functional extracted for a homogeneous electron gas (Ceperley and Alder, 1980) is “universal” and can be applied to an inhomogeneous gas. The procedure for generating a self-consistent field (SCF) potential is given in Fig. 6. The SCF cycle is initiated with a potential constructed by a superposition of atomic densities. These densities are then used to solve a Poisson equation for the Hartree potential and a density functional is used to obtain the exchange-correlation potential. A screening potential composed of the Hartree and exchange-correlation potentials is then added to the fixed ion-core pseudopotential, after which the one-electron Schrödinger equation, or Kohn-Sham equation, is solved. The resulting wave functions from this solution are then employed to construct a new potential and the cycle is repeated. In practice, the “output” and “input” potentials are mixed using a scheme that accounts for the history of the previous iterations (Broyden, 1965; Chelikowsky and Cohen, 1992).

Methods for constructing ion core pseudopotentials can be based on this density functional framework. The first step is to consider an electronic structure calculation for a free *atom*, including all the electrons. This is an easy numerical calculation as the atomic densities are assumed to possess spherical symmetry and the problem reduces to a one dimensional radial integration.

Once we know the solution for an “all electron” potential, we can *invert* the Kohn-Sham equation and find the total pseudopotential, i.e., one can “unscreen” the total potential and extract the ion core pseudopotential. This ion core potential, which arises from tightly bound core electrons and the nuclear charge, is not expected to change from one environment to another. It should be transferable from the atom to a molecular state to a solid state or liquid state. The issue of this transferability must be addressed according to the system of interest. An immediate issue focuses on the pseudo-wave functions, which can be used to define the corresponding ion core pseudopotential.

Suppose we insist that the pseudo-wave function be identical to the all-electron wave function outside of the core region. As a specific example, let us consider the 3s state for a silicon atom. We want the pseudo-wave function to be identical to the all electron state outside the core region

$$\phi_{3s}^p(r) = \psi_{3s}(r) \quad r > r_c, \quad (26)$$

where ϕ_{3s}^p is a pseudo-wave function and r_c defines the core size. This assignment will guarantee that the pseudo-wave function will possess properties identical to the all electron wave function, ψ_{3s} in the region away from the ion core.

For $r < r_c$, we alter the all-electron wave function. We are free to do this as we do not expect the valence wave function within the core region to affect the chemical properties of the system. We can make the pseudo-wave function smooth and nodeless in the core region. This will provide rapid convergence with simple basis functions. One other criterion is mandated. Namely, the integral of the pseudocharge density within the core should be equal to the integral of the all-electron charge density. Without this condition, the normalized pseudo wave function differs by a scaling factor from the all-electron wave function. Pseudopotentials constructed with this constraint are called “norm conserving” (Hamann et al., 1979). Since we expect the bonding in a solid to be highly dependent on the tails of the valence wave functions, it is imperative that the normalized pseudo wave function be identical to the all-electron wave functions.

There are many ways of constructing “norm conserving” pseudopotentials as within the core the pseudo wave function is not unique. One of the most straightforward construction procedures places conditions on the pseudo-wave functions and then inverts a density functional solution for the atom (Kerker, 1980; Troullier and Martins, 1991).

Fig. 7 An all electron and a pseudo-wave function for the silicon 3 s radial wave function.

Suppose one assumes the pseudo-wave function, $\phi_l^p(r)$ has the following properties:

$$\phi_l^p(r) = \begin{cases} r^l \exp(p(r)) & r \leq r_c, \\ \psi_l(r) & r > r_c. \end{cases} \quad (27)$$

$p(r)$ is taken to be a polynomial of the form:

$$p(r) = c_0 + \sum_{n=1}^6 c_{2n} r^{2n}. \quad (28)$$

This form assures us that the pseudo-wave function is nodeless and by taking even powers in the polynomial there is no cusp associated with the pseudo-wave function. The parameters, c_{2n} , are fixed by the following criteria: (a) The all-electron and pseudo-wave functions have the same valence eigenvalue. (b) The pseudo-wave function is nodeless and be identical to the all-electron wave function for $r > r_c$. (c) The pseudo-wave function must be continuous as well as the first four derivatives of the wave function at r_c . (d) The pseudopotential has zero curvature at the origin.

This approach to pseudopotential construction is easy to implement and to include other possible constraints. An example of an atomic pseudo-wave function for Si is given in Fig. 7 where it is compared to an all-electron wave function. Unlike the 3s all electron wave function, the pseudo-wave function has no nodes.

Once the pseudo-wave function is constructed, then the Kohn-Sham equation can be inverted to arrive at the ion-core pseudopotential

$$V_{ion,l}^p(r) = \frac{\hbar^2 \nabla^2 \phi_l^p}{2m \phi_l^p} - E_{n,l} - V_H(r) - V_{xc}[\rho(r)]. \quad (29)$$

The ion core pseudopotential is well behaved as ϕ^p has no nodes and does not vanish. However, the potential is state dependent and energy dependent. The energy dependence is usually weak. For example, the 4s state in silicon computed by the pseudopotential constructed from the 3s state is usually accurate. Physically this happens because the 4s state is extended and experiences the potential in a region where the ion core potential has assumed a simple $-Z_v e^2/r$ behavior. However, the state dependence through l is an issue, the difference between a potential generated via a 3s state and a 3p can be significant. In particular, for first row elements such as C or O, the nonlocality or state dependence is quite large as there are no p states within the core region. For the first row transition elements for such as Fe, this is also an issue as again there are no d -states within the core.

An additional advantage of the norm conserving potential concerns the logarithmic derivative of the pseudo-wave function (Bachelet et al., 1982). An identity exists

$$-2\pi \left((r\phi)^2 \frac{d^2 \ln \phi}{dE dr} \right)_R = 4\pi \int_0^R \phi^2 r^2 dr = Q(R). \quad (30)$$

Fig. 8 Ion core pseudopotentials for carbon generated by four different methods in real and reciprocal space: (A) Troullier and Martins (1991), (B) Kerker (1980), (C) Hamann et al. (1979) and (D) Vanderbilt (1985). The dotted and solid lines correspond to the s and p pseudopotentials, respectively.

The energy derivative of the logarithmic derivative of the pseudo-wave function is fixed by the amount of charge, Q , within a radius, R . The radial derivative of the wave function ϕ is related to the scattering phase shift from elementary quantum mechanics. For a norm-conserving pseudopotential, the scattering phase shift at $R = r_c$ and at the eigenvalue of interest is identical to the all-electron case as Q is the same for the all-electron potential and the pseudopotential. As a consequence, the scattering properties of the pseudopotential and the all-electron potential have the same energy variation to first order when transferred to other systems.

The pseudo wave function is not unique. This property was recognized early in its inception. For example, within the Phillips-Kleinman formulation, one can always add a function, f , to the pseudo-wave functions without altering the pseudopotential provided f is orthogonal to the core states. Consider the matrix element in Eq. 5. If one changes Φ_v^p to $\Phi_v^p + f$, then $\langle \Psi_c | \Phi_v^p + f \rangle = \langle \Psi_c | \Phi_v^p \rangle + \langle \Psi_c | f \rangle = \langle \Psi_c | \Phi_v^p \rangle$. Nothing is changed in the Phillips-Kleinman pseudopotential by this addition.

The non-uniqueness of the pseudopotential can be exploited to optimize the convergence of the pseudopotentials for the basis of interest. Much effort has been made to construct “soft” pseudopotentials. By “soft,” one means a “rapidly” convergent calculation using plane waves as a basis. Such potentials are characterized by a “large” core size, i.e., a large value for r_c . However, as the core becomes larger, the “goodness” of the pseudo-wave function can be compromised as the transferability of the pseudopotential becomes more limited. In Fig. 8, the ion core pseudopotential for carbon is plotted in real space and in reciprocal space. Although the potentials look quite different in the core region, they all give reliable electronic structure properties for carbon.

Pseudopotentials constructed within density functional theory are inherently nonlocal as they depend on the all electron state of the atom. This feature can also be included in empirical pseudopotentials using parameterized potentials (Cohen and Chelikowsky, 1989).

In setting up the eigenvalue problem, we need to include an additional matrix element in Eq. (22). One can consider a local potential as a reference potential. For example, we can write $\Delta V_l = V_{local} - V_l$, where V_{local} can be any local potential, but is often chosen to a specific component. As an example, suppose we have a carbon atom. We can find a pseudopotential for the s -state and take this as a local component. The p potential is then referenced as $V_s + \mathcal{P}_p^\dagger (V_p - V_s) \mathcal{P}_p$ where $\mathcal{P}_p$ is a projection operator that only acts on the $l = 1$ component of the wave function. In general, the nonlocal elements are very short ranged in real space as the size of the ion core is determined by r_c . Outside of the core the potential components converge to the same limit.

A major strength of density functional pseudopotentials is that they can be employed for systems with many atoms of low symmetry, e.g., clusters, liquids, and surfaces, without having to fit any form factors. However, a plane wave basis will require a large cutoff for such systems. In this case, the nonlocal matrix elements can be difficult to evaluate as elements depend on both $\vec{k} + \vec{G}$ and $\vec{k} + \vec{G}'$. An efficient form for the required nonlocal matrix elements (Kleinman and Bylander, 1982) is given by

$$\begin{aligned}
\Delta V_l^{KB}(\vec{k} + \vec{G}, \vec{k} + \vec{G}') &= \frac{\sum_m Y_{lm}^*(\vec{k} + \vec{G}) Y_{lm}(\vec{k} + \vec{G}')}{4\pi\Omega_a} \int \Phi_l^p(r) \Delta V_l(r) \Phi_l^p(r) dr \\
&\times \int \Phi_l^p(r) \Delta V_l(r) j_l(|\vec{k} + \vec{G}'|r) r^2 dr \\
&\times \int \Phi_l^p(r) \Delta V_l(r) j_l(|\vec{k} + \vec{G}|r) r^2 dr,
\end{aligned} \tag{31}$$

where Φ_l^p is the atomic reference pseudo-wave function and Y_{lm}^* is a spherical harmonic with the angles determined by the unit vector: $\vec{k} + \vec{G}$. This matrix element form has a great advantage as the integrals are separable in that they are solely a function of $\vec{k} + \vec{G}$ or a function of $\vec{k} + \vec{G}'$. The individual integrals can be stored and retrieved as required in setting up the matrix.

The Kohn-Sham problem can also be solved directly in real space (Chelikowsky et al., 1994). In this case the nonlocal matrix elements can be cast as

$$\begin{aligned}
\Delta V_l^{KB}(x, y, z) \phi^p(x, y, z) &= \sum_{lm} G_{lm} u_{lm}^p(x, y, z) \Delta V_l(x, y, z) \\
G_{lm} &= \frac{\int u_{lm}^p \Delta V_l \phi^p dx dy dz}{\int u_{lm}^p \Delta V_l u_{lm}^p dx dy dz},
\end{aligned} \tag{32}$$

where u_{lm}^p are the reference atomic pseudo-wave functions. The nonlocal nature of the pseudopotential is apparent from the definition of G_{lm} , the value of these coefficients are dependent on the pseudo-wave function, ϕ^p , acted on by the operator ΔV_l .

While our focus has been on “norm conserving” pseudopotentials, one can generalize the pseudopotential method. It is possible to make the pseudopotentials even weaker by relaxing this condition. (Vanderbilt, 1990) proposed such a method for constructing *ultra soft pseudopotentials*, which are constructed as a generalized eigenvalue problem. The norm conservation constraint is relaxed, and the charge density within the ion core is not explicitly considered as part of the pseudo-wave function. The relaxation of the norm conservation constraint allows one to consider a much larger core radius and a much softer potential.

One issue which is relevant for pseudopotential constructions, regardless of whether the potential is intended for use with a plane wave basis or not, concerns the issue of unbound, or weakly bound, atomic states. If an atom does not bind a state of interest, then the atomic wave function corresponding to this state is clearly not normalizable. Nonetheless, the pseudopotential corresponding to this state might be of some interest, e.g., in a crystal such diverging wave functions are “captured” by the potentials of neighboring atoms. For example, Ba has a strong *f*-component resonance. However, these *f*-states are not bound for neutral Ba atom. In order to bind such states, one must consider highly ionized atomic states, which result in very strong pseudopotentials. Sometimes these potentials are so strong as to be useless for a plane wave basis, or so far removed from the chemical environment of interest that their transferability may be suspect. Hamann (1989) has suggested a method for handling such cases by integrating out the Kohn-Sham equation to a large distance and at that point terminating the pseudo-wave function. The corresponding “terminated” wave function is then used to generate a pseudopotential for the component of interest.

Empirical pseudopotentials provide effective tools in understanding the optical and dielectric properties of semiconductor crystals (Cohen and Chelikowsky, 1989); however, to understand structural properties, we need to employ a different approach. Since the form factors in the empirical pseudopotential have been fit to optical transitions, there is no reason to believe that they will be very accurate for structural properties such as the phase stability, the equilibrium bond length, and the bulk modulus of a crystal. Pseudopotentials constructed within density functional theory can serve this purpose.

Evaluating the total energy of a crystal can be a difficult task. The total energy of the system contains terms that individually diverge, e.g., the repulsive Coulomb terms between the ion cores and the electron-electron interactions. These terms can be handled in Fourier or momentum space using a plane wave basis (Ihm et al., 1979). The total energy of the system can be written as

$$E_T = E_{kin} + E_{ec} + E_H + E_{xc} + E_{cc}. \tag{33}$$

E_T is the total electronic energy, E_{kin} represents the electronic kinetic energy, the electron-ion core interaction energy is given by E_{ec} , the electrostatic coulomb energy is given by the Hartree energy, E_H , the non-classical exchange-correlation energy is given by E_{xc} and the ion core-ion core classical term is given by E_{cc} . The momentum-space expressions for the electronic energy terms are as follows:

$$E_{kin} = \frac{1}{N} \sum_{n, \vec{k}, \vec{G}} \left| \phi_n^p(\vec{k} + \vec{G}) \right|^2 \frac{\hbar^2 |\vec{k} + \vec{G}|^2}{2m}, \tag{34}$$

$$E_{ec} = \frac{1}{N} \sum_{n, \vec{k}, \vec{G}} \phi_n^{p*}(\vec{k} + \vec{G}) \phi_n^p(\vec{k} + \vec{G}') \times \left(V_c^p(\vec{k} + \vec{G}, \vec{k} + \vec{G}') + \delta_{\vec{G}, \vec{G}'} \frac{1}{\Omega_c} \int \frac{Ze^2}{r} d^3r \right), \quad (35)$$

$$E_H = \frac{\Omega_c}{2} \sum_{\vec{G}, \vec{G} \neq 0} \frac{4\pi e^2}{G^2} |\rho(\vec{G})|^2, \quad (36)$$

$$E_{xc} = \frac{\Omega_c}{2} \sum_{\vec{G}} \rho^*(\vec{G}) \varepsilon_{xc}(\vec{G}), \quad (37)$$

$$E_{cc} = \frac{e^2}{2} \sum_{s, s'} Z_{v, s} Z_{v, s'} \left\{ \frac{4\pi}{\Omega_c} \sum_{\vec{G}, \vec{G} \neq 0} \left[\frac{1}{G^2} \cos(\vec{G} \cdot (\vec{\tau}_s - \vec{\tau}_{s'})) \times \exp\left(\frac{-G^2}{4\eta^2}\right) \right] - \frac{\pi}{\Omega_c \eta^2} + \sum_{\vec{R}, \vec{R} \neq 0} \left[\frac{\text{erfc}\left(\eta \left| \vec{R} - \vec{\tau}_s + \vec{\tau}_{s'} \right| \right)}{\left| \vec{R} - \vec{\tau}_s + \vec{\tau}_{s'} \right|} \right] - \frac{2\eta}{\sqrt{\pi}} \delta_{s, s'} \right\}. \quad (38)$$

Each term yields the energy per cell; N is the total number of cells, Ω_c is the cell volume, $\vec{R}$ is a lattice vector, $\vec{G}$ is a reciprocal lattice vector, Z is the total core charge, which is a sum of the individual core charges $Z_{v, s}$, $\vec{\tau}$ is the basis vector, $\vec{k}$ is the crystal momentum and ϕ_n^p is wavefunction for state n . $\rho(\vec{G}) V_c^p(\vec{k} + \vec{G}, \vec{k} + \vec{G}')$, and $\phi_n^p(\vec{k} + \vec{G})$ represent the Fourier components of the charge, ion core potential and the pseudo-wave function. The sums involving the pseudo-wave functions run only over the occupied states. η is parameter that controls the convergence of the Ewald summation in real space versus momentum space (Ihm et al., 1979).

In practice, it is easier to make use of the eigenvalue explicitly and subtract off the "double counting terms," i.e., one can write the total energy as

$$E_T = \frac{1}{N} \sum_{n, \vec{k}} E_n(\vec{k}) - E_H + \Delta E_{xc} + E_{cc}. \quad (39)$$

The sum is over all occupied states. The eigenvalue term contains the exchange-correlation term whereas the total energy should contain the exchange-correlation energy. This term can be written as

$$\Delta E_{xc} = \Omega_c \sum_{\vec{G}} \rho^*(\vec{G}) \left[\varepsilon_{xc}(\vec{G}) - V_{xc}(\vec{G}) \right], \quad (40)$$

where ε_{xc} is related to the exchange-correlation via a functional derivative:

$$\Delta V_{xc} = \frac{\delta(\rho \varepsilon_{xc}[\rho])}{\delta \rho}, \quad (41)$$

In the local density approximation (Kohn and Sham, 1965)

$$E_{xc}[\rho] = \int \rho(\vec{r}) \varepsilon_{xc}[\rho(\vec{r})] d^3r. \quad (42)$$

In the simplest formalism, ε_{xc} is extracted from a homogeneous electron gas (Kohn and Sham, 1965).

The total energy, E_T , for a crystal structure can be calculated using Eq. (39) as a function of the lattice constant and any internal structural parameters. This calculation can be used to find the equation of state for a given phase (Yin and Cohen, 1980). This approach represents a seminal point in condensed matter physics, e.g. it demonstrated a workable scheme for examining structural properties of solids and its extension led to molecular dynamics using quantum forces (Car and Parrinello, 1985).

The first application of phase stability using pseudopotential-density functional theory centered on a number of silicon crystal structures: face centered cubic, body centered cubic, hexagonal close packed, hexagonal diamond, cubic diamond, white tin and simple cubic. For each structure, the energy was minimized for a given volume by optimizing the internal coordinates, e.g., for a hexagonal structure the c/a ratio was optimized. Depending on the system studied the range of volumes considered is varied.

Fig. 9 Total electronic energy for seven phases of crystalline silicon as function of the atomic volume (Yin and Cohen, 1980). The volume has been normalized to the measure value of diamond. The dashed line is a common tangent of the energy curves for the diamond and β -tin phases. The total energy reference is the energy per pseudo Si atom.

The results are impressive when one considers that this is a calculation requiring only the atomic number and crystal structure as input. Generally, the pseudopotential-density functional method yields lattice constants and bulk moduli to an accuracy of about 1% and 5%, respectively. The cohesive energy can be calculated by comparing the total energy at the equilibrium lattice constant with the energy of the isolated atoms. Spin polarization effects (von Barth and Hedin, 1972; Gunnarsson et al., 1974) and zero point vibrational energy need to be considered. Early results computed within the local density approximation gave reasonable estimates of the cohesive energies; however, in general the generalized gradient approximation yields more accurate cohesive energies (Becke, 1992).

The total energy versus volume curves for seven crystal phases of silicon and are shown in Fig. 9. The lowest energy state corresponds to the diamond structure, which is observed experimentally under ambient conditions. As with any such calculation, there is no guarantee that there is an untried structure with a lower energy state.

For small volumes other structural phases are lower in energy than the diamond phase, hence pressure induced solid-solid structural phase transitions are predicted. As hydrostatic pressure is applied the path indicated in the figures, $1 \rightarrow 2 \rightarrow 3 \rightarrow 4$, illustrates the change from diamond at 1 to β -tin at 4, with the transformation occurring along the $2 \rightarrow 3$ segment of the path where both structures can coexist. The predicted phase transition pressure for the diamond $\rightarrow$ β -tin phase is 99 kbar; the measured values are 125 and 100 kbar, respectively (Yin and Cohen, 1982).

The successful prediction of high pressure structural phases such as hexagonal forms of Si and Ge and fcc Si are one of the impressive results of the pseudopotential-density functional theory calculations (Chang and Cohen, 1984). Moreover, these high pressure phases are metallic and predicted to be superconductors (Chang et al., 1985). Since these calculations, total energy computations using pseudopotentials constructed within density functional theory have become routine for a wide variety of materials.

As with any computational approach, an accurate solution is limited by the least accurate approximation. In the case of density functional pseudopotentials, the weakest aspect centers on the nature of the exchange-correlation functional. For example, computations for highly correlated systems are likely to fail. A pseudopotential constructed within a given functional will accurately reproduce a solution of the functional, but if the functional is flawed the pseudopotential will reflect his flaw.

In contrast to density functional theory, the accuracy of the pseudopotential can be validated by replacing it with an all electron potential and assessing any differences. What cannot be done is to take an approximate density functional and replace it with an exact functional, as an exact functional does not exist, save in limiting cases like a homogeneous electron gas.

Conclusion

The pseudopotential concept has had a profound impact on our understanding of the electronic structure of semiconductors. In this chapter, both empirical and density functional pseudopotential concepts were outlined and some central applications discussed.

Empirical pseudopotentials provided a means for understanding the optical and dielectric properties of semiconductors and the underlying energy band structures. It is sometimes stated that the empirical pseudopotential method (EPM) established the validity of the energy band concept for solids in general. There is truth to this statement. In the 1950s, there were extended discussions about the validity of the one electron picture and whether it could be applied to solids and specifically to semiconductors such as silicon. Some workers thought that the electron-hole interactions for a optical excitation would be so strong as to obscure any attempt at understanding such excitations using energy band theory. Given that the EPM allowed adjustments to the one electron potential, if the EPM had failed to work with the flexibility of choosing a potential, one would have questioned whether it was possible to construct a meaningful one-electron potential and corresponding energy band structure. The consequences of this failure would have been very damaging to prospects for using energy bands to interpret optical, dielectric, photoemission, and transport properties of semiconductors.

Fortunately, this was not the case, the EPM provided a simple and effective way to couple band structure theory to experimental work and its impact was immediate. While much of this effort took place in the 1960s and 1970s, the EPM still serves as an effective means to interpret optical data for semiconductors. While more sophisticated methods now exist to examine optical properties, few of the conclusions of the EPM have been overturned by these methods.

The coupling of density functional theory with pseudopotentials in the early 1980s resulted in another impressive advance for understanding the electronic structure of materials. The accuracy of density functional theory for predicting electronic and structural energies was problematic at that time. However, the direct numerical application to structural energies to problems involving bond lengths, compressibilities, phonon modes, and phase stabilities showed conclusively the applicability of pseudopotential methods to these problems. Over the last 10 years, more than 10,000 papers have appeared with pseudopotentials in the title or abstract and these papers have been cited over 100,000 times.

The future of pseudopotentials constructed within density functional theory clearly depend on advances in creating more accurate functionals. One proposed advance centers on mixing exact exchange with local density functionals (Perdew et al., 1996). These so called hybrid functionals should capture nonlocal contributions and result in a more accurate description of the many electron problem. Of course, such approaches can be computationally complex to implement. As these difficulties are overcome (Boffi et al., 2016), pseudopotentials constructed within hybrid functionals will become more commonplace.

The vitality and future of the pseudopotential method is without question. The method is now used to examine new and exciting materials systems. These systems include nanoscale systems, amorphous solids, glasses, and liquids. Moreover, owing to strong advances in both hardware and software (algorithms) it is now possible to address systems with thousands of atoms on an almost routine basis (Liou et al., 2021).

Abstract

The effective mass of a particle in an energy band is its inertia due to the interaction with the lattice during its motion through the crystal. Effective masses are important quantities to parameterize the band structure of materials and their electronic properties like the intrinsic carrier concentrations as function of temperature, electrical conductivity, speed of integrated circuits or the efficiency of solar cells. This chapter aims to review the basic principles and quantum theory behind the concept of effective mass in solid state physics.

Key points

- Effective mass theory
- Envelope function approximation
- Density-of-states effective mass
- Effective mass in Dirac cones

Introduction

Electrons move very differently in a periodic lattice than when they are free in space. In vacuum, the electron mass is a fundamental constant of nature given by $m_0 = 9, 11 \times 10^{-31}$ kg. In crystalline solids, electrons sense the environment and interact with (i) the lattice atoms, (ii) other electrons moving around the lattice, and (iii) with vibrations of the lattice. As a consequence of all these interactions, electrons move as if their mass was different from m_0 . This is the most fundamental idea behind the concept of effective masses.

The well-known single particle energy of free electrons is

$$E(\vec{k}) = \frac{\hbar^2 k^2}{2m_0}, \quad (1)$$

where $\vec{k}$ is the electron wave vector (Ashcroft and Mermin, 1976). In a crystal close to an energy band extremum, the single particle energy of electrons including the effect of all interactions with the surroundings can be described as

$$E(\vec{k}) = \frac{\hbar^2 k^2}{2m^*}, \quad (2)$$

where m^* is the effective mass of the electron in the crystal. Such a surprisingly simple result is successful in describing many physical phenomena in crystalline condensed matter. In fact, effective masses provide a very useful and powerful way to parameterize solid state materials like semiconductors and insulators.

Electron dynamics

In a crystalline solid, electrons occupy electronic states characterized by their wave vector $\vec{k}$ and a band index n . The energy in any band is a quasi-continuous function $E_n(\vec{k})$, and the ensemble of functions $E_n(\vec{k})$ constitutes the energy band structure of a given crystal. Due to the periodicity of the lattice, a quantum state may be described by a Bloch function $\psi_{n,\vec{k}}(\vec{r}) = u_{n,\vec{k}}(\vec{r})e^{i\vec{k}\cdot\vec{r}}$, that satisfies the Schrödinger equation $[\hat{p}^2/2m + V(\vec{r})]\psi_{n,\vec{k}}(\vec{r}) = E_n(\vec{k})\psi_{n,\vec{k}}(\vec{r})$, where $V(\vec{r})$ is the periodic potential energy created by the crystalline lattice.

As the electronic states $\psi_{n,\vec{k}}(\vec{r})$ extend over the whole crystal with the same periodicity as the lattice, it may not be very insightful to describe the dynamics of electrons. Instead, one constructs a moving wavepacket localized in space, whose group velocity is given by

$$\vec{v}_n = \frac{1}{\hbar} \nabla_{\vec{k}} E_n(\vec{k}), \quad (3)$$

where the index n indicates that the wavepacket was constructed with $\psi_{n,\vec{k}}(\vec{r})$ states belonging to a single energy band (it will be dropped in the following analysis). The acceleration of this wavepacket is then given by:

$$\vec{a} = \frac{d\vec{v}}{dt} = \frac{1}{\hbar} \frac{d}{dt} \nabla_{\vec{k}} E(\vec{k}) = \frac{1}{\hbar} \left(\frac{d\vec{k}}{dt} \cdot \nabla_{\vec{k}} \right) \nabla_{\vec{k}} E(\vec{k}) = \frac{1}{\hbar^2} H_E(\vec{k}) \frac{d(\hbar\vec{k})}{dt}, \quad (4)$$

where $H_E(\vec{k})$ is the Hessian matrix, whose elements are given by $H_E^{(i,j)}(\vec{k}) = \partial^2 E(\vec{k}) / \partial k_i \partial k_j$. An external force acting on the wavepacket is given by $\vec{F} = d(\hbar\vec{k})/dt$, where $\vec{p} = \hbar\vec{k}$ is the electron momentum. Comparing Eq. (4) with Newton's second law $\vec{a} = \vec{F}/m$, one obtains that the electron mass is replaced by an effective mass tensor m^* , whose elements are given by:

$$m_{ij}^* = \left(\frac{1}{\hbar^2} \frac{\partial^2 E(\vec{k})}{\partial k_i \partial k_j} \right)^{-1}. \quad (5)$$

Eq. (5) indicates that the effective mass is inversely proportional to the curvature of the band structure. Large curvatures imply small effective masses, and vice-versa. The importance of this result is paramount: It indicates that despite the complexity of the multiple interactions undergone by electrons across the crystal, they all can be accounted for by a single parameter in their dynamics. The tensor nature of the effective mass indicates that materials can be anisotropic, i.e., their properties depend on orientation of the material's body.

Band curvature and types of charge carriers

In a typical band structure, shown in Fig. 1, there are many energy bands for which curvatures vary as function of $\vec{k}$. Hence, near the bottom of any band the curvature is positive, whereas near the top of any band the curvature is negative. This indicates that the effective masses can be either positive or negative.

Fig. 1 Schematics of a semiconductor energy band structure.

In pure dielectric materials at $T = 0$ K, there are just enough electrons to fill the valence band, and no electrons to occupy the conduction band. The band gap E_G provides a primary indication of the metallic, semiconductor, or insulator character of materials. $E_G \geq 3.5$ eV are representative of insulators, $E_G \approx 0$ eV are found in metallic materials and E_G ranging between 0.3 eV and 3.5 eV are typical of semiconductor materials. One important feature of the band structure of real materials is that the maximum of the valence band (VBM) and the minimum of the conduction band (CBM) may be located at distinct $\vec{k}$ points in the reciprocal space. If so, they are called indirect gap materials, otherwise they are called direct gap materials.

At finite temperatures, some of those electrons occupying the top of the valence band are transferred across the band gap to the bottom of the conduction band, leaving unoccupied states behind in the valence band. Particles occupying conduction band states exhibit positive effective mass, and are called electrons. On the other hand, particle occupying valence band states are called holes, and exhibit negative effective mass. This means that holes act as if they were positively charged and are accelerated by an external electric field in the reverse direction expected for electrons. Usually, the top of the valence band is degenerate exhibiting energy bands with different curvatures, giving rise to the heavy-hole (smaller curvature) and light-hole (larger curvature bands). There is even a third type of hole band called spin-orbit split-off band, which arises from the spin-orbit interaction. In general, the effective masses of electrons and holes are different.

Parabolic band approximation

Near band edges, like the top of the valence band and/or bottom of the conduction band, $E(\vec{k})$ can be expanded into Taylor series. For simplicity, we temporarily assume that k is a scalar

$$E(k) = E(k_0) + (k - k_0) \left. \frac{dE}{dk} \right|_{k_0} + \frac{(k - k_0)^2}{2} \left. \frac{d^2E}{dk^2} \right|_{k_0} + O[(k - k_0)^3], \quad (6)$$

where k_0 is the position of the band edge in the reciprocal space. We keep in mind that the energy bands at the band edges are extrema ($[dE(k)/dk]_{k_0} = 0$), and that the energy states above/below few $k_B T$ of the band edges are hardly occupied at finite temperatures. We can disregard high order terms $O[(k - k_0)^3]$ in the above expansion to obtain the well-known parabolic band approximation

$$E(k) - E(k_0) = \frac{(k - k_0)^2}{2} \left. \frac{d^2E}{dk^2} \right|_{k_0} = \frac{\hbar^2 (k - k_0)^2}{2m^*}, \quad (7)$$

where we used the definition of the effective mass in terms of the band curvature near $k = k_0$. One should note that the parabolic band approximation is similar to the energy dispersion of the free electrons replacing m_0 by m^* in Eq. (1). Recovering the vector form of k , the parabolic band approximation becomes:

$$E(\vec{k}) = E(\vec{k}_0) + \frac{\hbar^2}{2} (\vec{k} - \vec{k}_0) \cdot \left(\frac{1}{m^*} \right) \cdot (\vec{k} - \vec{k}_0), \quad (8)$$

where the effective mass is written in the tensor form whose elements are given by Eq. (5).

We are now in position to describe some few cases of energy bands in terms of effective masses. The simplest possible case is for isotropic direct gap materials (e.g., GaAs, InAs) whose band edges are located at Γ point ($\vec{k}_0 = 0$) in the Brillouin zone. In this case, the conduction, light-hole, heavy hole, and split-off bands are respectively given by:

$$E_c(\vec{k}) = E_c(0) + \frac{\hbar^2 k^2}{2m_c^*}, \quad (9)$$

$$E_{lh}(\vec{k}) = E_v(0) + \frac{\hbar^2 k^2}{2m_{lh}^*}, \quad (10)$$

$$E_{hh}(\vec{k}) = E_v(0) + \frac{\hbar^2 k^2}{2m_{hh}^*}. \quad (11)$$

$$E_{so}(\vec{k}) = E_v(0) + \frac{\hbar^2 k^2}{2m_{so}^*}. \quad (12)$$

In the above equations, m_c^* , m_{hh}^* , m_{lh}^* and m_{so}^* represent the effective masses of electrons, heavy-holes, light-holes and split-off band, respectively. Δ_0 is the spin-orbit split-off energy, and the band gap is given by $E_G = E_c(0) - E_v(0)$.

For indirect gap materials (e.g., Si, Ge), the VBM is located at the Γ point, but the CBM is located away from the Brillouin zone center. In this case, the light-hole and heavy-hole bands are considered reasonably isotropic, and can be described in the same way of Eqs. (10) and (11). However, the CBM is degenerated, highly anisotropic and can be written as

$$E_c(\vec{k}) = E_c(\vec{k}_0) + \frac{\hbar^2 k_x^2}{2m_l^*} + \frac{\hbar^2 (k_y^2 + k_z^2)}{2m_t^*} \quad (13)$$

where $\vec{k}_0$ is located near the X of the Brillouin zone for Si, and at L point for Ge. Those are symmetric points with six degenerated equivalent directions. k_x is measured from the CBM and it is oriented along the ΓX direction for Si, and along ΓL direction for Ge.

Table 1 Effective masses of some of the most common semiconductors.

Material	m_e^*/m_0	m_{hh}^*/m_0	m_{lh}^*/m_0	m_{so}^*/m_0
Si	0.91 (0.19)	0.49	0.16	0.24
Ge	1.58 (0.082)	0.33	0.043	0.084
C	1.40 (0.36)	2.12	0.7	1.06
GaAs	0.063	0.51	0.082	0.15

$k_{y,z}$ lie along perpendicular directions with respect to k_x . m_l^* and m_t^* refer to longitudinal and transverse effective masses with respect to direction connecting Γ point and the position $\vec{k}_0$ of the CBM. Table 1 lists the effective masses of some of the most common elemental and compound semiconductors.

Effective mass theory

Although we have described the concept of effective masses phenomenologically so far, there is a solid theoretical framework behind it. Consider the general Schrödinger equation for a Bloch state $H(\vec{r})\Psi_{n,\vec{k}}(\vec{r}) = E_n(\vec{k})\Psi_{n,\vec{k}}(\vec{r})$, where $\psi_{n,\vec{k}}(\vec{r}) = u_{n,\vec{k}}(\vec{r})e^{i\vec{k}\cdot\vec{r}}$. Written in terms of $u_{n,\vec{k}}(\vec{r})$, it becomes

$$\left[H_0 + \frac{\hbar^2}{m_0} \vec{k} \cdot \vec{p} \right] u_{n,\vec{k}}(\vec{r}) = \left[E_n(\vec{k}) - \frac{\hbar^2 k^2}{2m_0} \right] u_{n,\vec{k}}(\vec{r}). \quad (14)$$

where $H_0 = \frac{p^2}{2m_0} + V(\vec{r})$ is the unperturbed crystal Hamiltonian, and $H_1 = (\hbar^2/m_0)\vec{k} \cdot \vec{p}$ is a perturbation. The unperturbed problem obeys $H_0 u_{n,0}(\vec{r}) = E_n(0)u_{n,0}(\vec{r})$. The time-independent perturbation theory gives the energy to 2nd order in perturbation:

$$E_n(\vec{k}) = E_n(0) + \frac{\hbar^2 k^2}{2m_0} + \frac{\hbar^2}{m_0^2} \sum_{n' \neq n} \frac{|\vec{k} \cdot \vec{p}_{n,n'}|^2}{E_n(0) - E_{n'}(0)}, \quad (15)$$

where $\vec{p}_{n,m} = \langle u_{n,0} | \vec{p} | u_{m,0} \rangle$ is the momentum matrix element. The first order correction $E_n^{(1)}(\vec{k}) = (\hbar/m_0)\vec{k} \cdot \vec{p}_{n,n}$ vanishes because $\vec{p}_{n,n} = 0$ due to symmetry considerations. This equation can be written as:

$$E_n(\vec{k}) = E_n(0) + \frac{\hbar^2}{2} \sum_{\alpha,\beta} \left(\frac{1}{m^*} \right)_{\alpha\beta} k_\alpha k_\beta, \quad (16)$$

where

$$\left(\frac{1}{m^*} \right)_{\alpha\beta} = \frac{1}{m_0} \delta_{\alpha\beta} + \frac{2}{m_0^2} \sum_{n' \neq n} \frac{p_{n,n}^\alpha p_{n',n}^\beta}{E_n(0) - E_{n'}(0)}. \quad (17)$$

Although the above expression was developed for a band whose edge is located at $\vec{k} = 0$, it is valid for any location $\vec{k}_0$.

The above theory is based on non-degenerated time-independent perturbation theory, and it needs modification in order to accurately include the light-hole, heavy-hole and spin-orbit bands. Further accuracy can be obtained by noticing that the functions $u_{m,\vec{k}_0}$ (for a given $\vec{k}_0$) deliver a complete set of eigenfunctions. The eigenfunctions $u_{n,\vec{k}}$ can be expressed as linear combination of $u_{m,\vec{k}_0}$, for a proper choice of $\vec{k}_0$, and the Eq. (14) can be solved using this basis set. This approach gave rise to widely used models in the literature as Kane and Luttinger-Kohn models (Chuang, 1995; Kane, 1966; Luttinger and Kohn, 1956).

Heterostructures

One of the most important consequences of the effective mass theory is the *envelope function approximation* to study the electronic properties of heterostructures (e.g., quantum wells, wires and dots). In this approach, the single band effective Schrödinger equation for the whole heterostructure is written as (Bastard, 1988; Burt, 1992):

$$\left[-\frac{\hbar^2}{2} \nabla \left(\frac{1}{m^*(\vec{r})} \right) \nabla + U(\vec{r}) \right] F(\vec{r}) = EF(\vec{r}) \quad (18)$$

where $U(\vec{r})$ is the heterostructure potential constructed from the alignment of band gaps at the interfaces of different materials and/or an external potentials, $m^*(\vec{r})$ is the position-dependent effective mass, E is measured from the band edge of the quantum well (QW) region, and $F(\vec{r})$ is known as envelope wavefunction. In the envelope function approximation, the atomistic description of the different materials in the heterostructure are embedded in their effective masses. The approximate atomistic wavefunction is linked to the envelope wavefunction as $\psi(\vec{r}) = F(\vec{r}) u_{n,\vec{k}_0}(\vec{r})$, where $\vec{k}_0$ is the position of the band edge for which the envelope function description is being constructed. The presence of boundaries between materials demands the application of continuity boundary conditions in the envelope function $F(\vec{r})$ and in the quantity $[m^*(\vec{r})]^{-1} \nabla F(\vec{r})$ at the interfaces between materials.

Fig. 2 shows an example of how the alignment of band structures in the assembly of a QW heterostructure gives rise to a position-dependent effective mass. If the QW is thin enough (up to few tens of nanometers), discrete energy states in the conduction and valence bands appear in the QW region in the direction of confinement. Assuming infinite confinement barriers, those energy states measured from the bottom of their respective band edges, are given by:

$$E_n^v = \frac{\hbar^2}{2m_v^*} \frac{\pi^2}{L^2} n^2. \quad (19)$$

where $v = e, hh, lh$, and L is the QW width.

Density of states and carriers concentration

The concentration of mobile carriers in the conduction (n) and valence (p) bands are given by:

$$n = \int_{E_c}^{\infty} g_c(E) f(E) dE, \quad (20)$$

Fig. 2 Schematics of band alignment and position-dependent effective mass in heterostructures.

$$p = \int_{-\infty}^{E_v} g_v(E) [1 - f(E)] dE, \quad (21)$$

where $g_{c,v}(E)$ are the density of states in the conduction and valence bands, respectively. $f(E) = 1/(1 + e^{-(E-E_f)/k_B T})$ is the Fermi-Dirac distribution, E_f is the Fermi energy, k_B is the Boltzmann constant, and T the absolute temperature. The density of states $g_v(E)$ ($v = c, v$) represents the number of states per unit volume per unit energy in v band, and it is obtained by counting all states in the reciprocal space for each energy band. Assuming the parabolic band approximation, the respective densities of states (DOS) are given by:

$$g_c(E) = \frac{1}{2\pi^2} \left(\frac{2m_e^*}{\hbar^2} \right)^{3/2} \sqrt{E - E_c} \quad (E > E_c), \quad (22)$$

$$g_v(E) = \frac{1}{2\pi^2} \left(\frac{2m_h^*}{\hbar^2} \right)^{3/2} \sqrt{E_v - E} \quad (E < E_v). \quad (23)$$

For anisotropic materials, m_e^* and m_h^* may be slightly different from the values obtained from the curvatures of the band structure. For Si, for example, the DOS effective mass becomes $m_e^* = (m_l m_t)^{1/3}$. Solving Eqs. (20) and (21) for nondegenerate semiconductors i.e., $(E_c - E_f) \geq 3k_B T$ and $(E_f - E_v) \geq 3k_B T$, one obtains

$$n = N_c e^{-(E_c - E_f)/k_B T}, \quad (24)$$

$$p = N_v e^{-(E_v - E_f)/k_B T}. \quad (25)$$

N_v ($v = c, v$) is known as the effective density of states in each band, and they are given by:

$$N_v = 2 \left(\frac{m_v^* k_B T}{2\pi\hbar^2} \right)^{3/2} \quad (26)$$

In intrinsic (pure) materials, for every electron in the conduction band there is a hole in the valence band. This equilibrium condition is commonly written as $n = p = n_i$, where n_i is the intrinsic carrier concentration. Applying the condition $np = n_i^2$ (that holds even for doped materials), one obtains:

$$n_i = \sqrt{N_c N_v} e^{-E_g/2k_B T}. \quad (27)$$

The above quantities provide a drastically simplified method to parameterize carriers concentrations of solid state materials in terms of their effective masses, energy gap and temperature.

Two-dimensional materials

The recent discovery of graphene and other two dimensional (2D) materials (e.g., phosphorene, transition metal dichalcogenides, boron nitride just to mention a few) motivated huge efforts to investigate their electronic properties and to develop practical applications with those materials. Nowadays, there is a plethora of reported 2D materials with a wide variety of properties, ranging from metallic to semiconductors (Miró et al., 2014).

In 2D materials, the definition of effective masses in terms of band curvature (Eq. 5) still holds with a few important differences. The most intriguing difference is found in graphene, whose band structure exhibit linear dispersion, i.e., $E(\vec{k}) \propto k$ near the Fermi energy forming the so called Dirac cones, for which the absence of band curvature clearly results in an infinite effective mass. On the other hand, electrons in graphene are said to be *massless* in a clear contradiction with the conventional solid state definition of effective mass. This confusion is explained if we consider electrons in graphene as relativistic particles, for which the energy-momentum relationship is given by $E^2 = (pc)^2 + (m_0 c^2)^2 = (\hbar k c)^2 + (m_0 c^2)^2$, where m_0 is the rest mass of the particle. For *massless* particle we simply obtain $E = \pm \hbar k c$. Such a linear energy dispersion of *massless* relativistic is similar to the band structure of graphene at low energies.

In practice, cyclotron resonance measurements have shown that the electrons in graphene are not massless (Novoselov et al., 2005), and the electronics properties of graphene are better described by Dirac equation rather than Schrödinger equation. Thus, the alternative definition of effective mass for materials exhibiting linear band structure is (Ariel and Natan, 2012)

$$m^* = \hbar^2 k \left(\frac{dE(k)}{dk} \right)^{-1}. \quad (28)$$

As for 2D materials with non-diverging effective masses defined by Eq. (5), the most important difference is the absence of heavy-hole, light-hole and spin-orbit split-off bands as compared to three-dimensional materials.

Measurement methods

Effective masses have been traditionally measured using cyclotron resonance (Dresselhaus et al., 1955). In this method, the microwave absorption of an electron moving in an orbit perpendicular to a static magnetic field exhibits a peak at $\omega_c = \frac{eB}{m^*}$,

where e is the electron charge, and B is the magnetic field intensity. The effective mass can be also determined by methods that directly measure the band structure $E(\vec{k})$ like low energy angular-resolved photoemission spectroscopy (ARPES) (Damascelli, 2004).

Measurements of specific heat C_v in Fermi systems can be also used to determine the effective mass. At very low temperatures, the phonons contribution to C_v becomes negligible, and C_v becomes dominated by the electronic contribution. At this regime, one has $C_v = \pi^2 k_B^2 g(E_f) T/3$, where $g(E_f)$ is the density of states at the Fermi energy (Ashcroft and Mermin, 1976). Using Eq. (22), one obtains $C_v = k_B^2 k_f m_e^* T/3\hbar^2$, where k_f is the radius of the Fermi sphere in the reciprocal space. However, thermodynamic experiments are not able to distinguish directional effective masses, and the values estimated from C_v represent the DOS effective mass.

Effective masses are also helpful for the analysis of other experiments associated to electronic properties:

- The electrical conductivity σ is given by

$$\sigma = \frac{ne^2\tau}{m_e^*}, \quad (29)$$

where n is the density of mobile electrons, τ is a transport relaxation time. An electrical conductivity for holes can also be determined by replacing m_e^* by m_h^* and n by p , where p is the density of mobile holes. In the most general case where electrons and holes contribute to the charge transport, the total conductivity is $\sigma = \sigma_e + \sigma_h$. For anisotropic materials, the electrical conductivity assumes a tensor form.

- Plasma oscillation is a collective excitation of all available mobile electrons whose oscillation frequency (also known as plasma frequency) is:

$$\omega_p^2 = \frac{ne^2}{m_e^*\epsilon} \quad (30)$$

where e is the electron charge, and ϵ is the dielectric permittivity of the material.

- Excitons are fundamental electronic excitations associated to bound states of e-h pairs acting as a hydrogen-like atom. The exciton binding energy is given by:

$$E_b = \frac{\mu}{m_0} \frac{\epsilon_0^2}{\epsilon^2} \frac{R_y}{n^2} \quad (n = 1, 2, 3, \dots) \quad (31)$$

where $R_y = 13.6$ eV is the Rydberg energy, and $\mu = m_e^* m_h^* / (m_e^* + m_h^*)$ is the reduced effective mass of the exciton.

Conclusion

In conclusion, effective mass is a cornerstone concept of condensed matter physics whose importance and applicability is far greater than what it is possible to cover in such a short chapter. The beauty of the effective mass theory relies on the fact that it provides a rather simple method to describe materials in terms of a reduced number of parameters (e.g., band gap energy and band curvatures at high symmetry points of the Brillouin zone). Perhaps its most important practical consequence is the envelop function approximation that allows to accurately model the electronic and transport properties of quantum heterostructures, which are ubiquitous in modern technologies.

Abstract

Defects in insulators control properties of materials and devices. We first define the main issues and describe the theoretical methods for calculating defect electronic structure. Then we describe the main point defect types and consider how defect electrons couple to the motion of nearby ions. The concepts of electron and hole localization and self-trapping of polarons and excitons are introduced next. Properties of defects in disordered systems are briefly outlined and key points concerning defects at surfaces and interfaces are discussed including the dependence of the defect charge state on the position of the system Fermi energy. Finally, a short outlook is provided.

Key points

- Outline the main issues pertaining to defects in materials and defect types
- Define the main structure parameters of interest
- Outline the main theoretical models and methods used to study defect properties
- Introduce the electron-lattice coupling
- Describe intrinsic and extrinsic polaron and exciton localization and self-trapping
- Outline properties of defects in disordered materials
- Describe the main defect-induced properties of surfaces and interfaces

Introduction

Serious studies of materials are often serious studies of defects, for control of properties of materials implies control of defects or impurities. Understanding the electronic structure of defects in insulators has helped the development of microelectronic and quantum devices, the photographic process, solid electrolytes, and the applied surface physics of sensors and catalyst substrates (Crawford and Slifkin, 1972; Fleetwood et al., 2009; Hayes and Stoneham, 1985; Lannoo and Bourgoin, 1981; Stoneham, 1975). Here we will focus mainly on *point defects*, but dislocations and grain boundaries are very important too. The understanding of defect properties is based on a synthesis of theories, modelling, and experiment.

Defining the issues. Some of the common point defects are shown schematically in Fig. 1. They can be created in different charge states and undergo transformations during the lifetime of materials and devices. When a new material is created, which defects are important? Will there be vacancy-interstitial pairs (Frenkel defects) or just vacancies of several types (Schottky defects)? Will there be non-standard ionic charge states, like $3+ \text{Fe}$ ions in FeO ? Could one species move on to the sites of another, e.g. As antisites on Ga sites in GaAs? Can the material be doped with electrically-active impurities? Are there understandable trends of properties from material to material in some class, like II-VI compounds? Electronic structure is subtle and varied, with the key ideas identified by a mix of theory and experiment.

In most insulators Coulomb energies dominate, so antisite defects are not energetically easy, and charge transfer across sublattices is difficult, instead non-stoichiometry is common. Thus vacant lattice sites (*vacancies*), ions placed at normally unoccupied sites (*interstitial ions*), foreign ions present as impurity or dopant, and ions with charges different from those of the

[☆]Change History: September 2022. J Strand and AL Shluger prepared the update. Figs. 1, 3, 5, 7, 8 are new. All chapters and figures have been updated.

Fig. 1 Schematic of basic defect types in a binary insulator AB. (A) and (C) are vacancies of atoms type A and B, respectively. (B) An impurity atom on the site of atom A. (D) and (E) are two types of interstitial configurations of atom A: (D) – self-interstitial and (E) dumbbell interstitial. A pair of vacancy and interstitial defects, such as (A) + (D) or (A) + (E), is called a Frenkel pair. A pair of vacancies of atoms A and B, such as (A) + (C), is called a Schottky pair. (F) is a pair of anti-site defects, where the atom of type B occupies the site of the atom type A and the atom of type A occupies the site of the atom type B.

host ions are prevalent defect types (Fig. 1). Electronic defects may arise either as ions with charges deviating from those on lattice ions, or from excitation of electrons from filled valence bands to empty conduction bands. When a valence-band electron is missing, one has an electron hole (*hole*) and its behavior can be compared with that of an electron in a normally empty conduction band. Electron and hole together can form a transient neutral species, the *exciton*. In the absence of macroscopic electric fields or irradiation, ionic lattices must be electrically neutral overall, implying that one charged defect must be compensated by another charged defect or defects to satisfy the electro-neutrality condition locally or over the whole sample. The charges of defects and of the regular lattice particles, defined with respect to the neutral ideal lattice, are called *effective charges*.

Complexity is the norm for advanced materials. When solid-state lasers degrade, when mechanical properties change under irradiation, defect processes occur in parallel on timescales from femtoseconds upwards. In a composite material, defect phenomena may happen in the matrix, the fiber or at the interface. When a metal is oxidized, interfacial, diffusional and impurity processes co-exist. Separating these processes by experiment alone may not be feasible. The electronic structure theory establishes priorities, and is used to organize and analyze massive amounts of data, to identify what is novel and point to significant issues.

Which electronic structure parameters are of interest? Defects control the properties and performance of materials and devices in various ways. For luminescence, whether of rare earths in oxides or sulfides or CsI:Na, the spectroscopic properties of impurities, optical absorption and luminescence energies, are of the utmost importance. Bragg grating formation in silica fibers is associated with the optical absorption of induced defects. Defect species in gate dielectrics, such as oxygen vacancies, impurities and hydrogen, influence device performance. In microelectronic devices these defects may initiate degradation, trap charge, or create fixed charge, which scatters carriers in the Si substrate. Their electron and hole trapping energies and cross-sections are of main interest. Many radiation-induced processes in insulators involve forming self-trapped excitons and holes, so the electron coupling to lattice deformation plays a crucial role. Designing *qubit* formation in wide band gap insulators requires deep defect states which can be initialized, manipulated, and measured with high fidelity at room temperature. Among other criteria, they should possess optical transitions that do not introduce interference from the electronic states of the host. In photovoltaic materials, except for selected dopants, defects often have detrimental effects and should be eliminated to minimize charge recombination. On the other hand, in photocatalysis defects often play an active role by stabilizing charge separation and mediating rate-limiting catalytic steps.

Experimental defect characterization is vital for our understanding which defects influence the optical, magnetic and electrical properties of materials. A broad range of characterization techniques includes vibrational spectroscopy, electron paramagnetic resonance (EPR), optical techniques, e.g. photoluminescence spectroscopy, and electrical techniques, such as deep-level transient spectroscopy (DLTS), as well as optoelectrical techniques, e.g. photocurrent spectroscopy (Bassani and Pastori Parravicini, 1975; Fleetwood et al., 2009; Spaeth and Overhof, 2003; Toyozawa, 2003; Weil and Bolton, 2007). Each method has its advantages and disadvantages. Therefore, the different methods complement each other as there is not a single method to fully characterize any defect. The raw data of defect studies describe spectroscopic observations and their dependence on time and other parameters, such

as dopant concentration, temperature, pressure, irradiation power and dose. Carefully-obtained data provide the basis for formulating *defect models*. Fig. 2 shows several such models for major paramagnetic defects in irradiated fused silica. The most reliable models knit together the best-available experimental data from many sources with solid-state physics theory, often aided by detailed calculations. Some of the key ideas underpinning modern calculations of the electronic structure of point defects in insulators are reviewed here. We start from outlining some of the theoretical methods used to study defect electronic structure. Then we review some of the concepts necessary for understanding the electronic properties of point defect in crystalline and disordered solids and at interfaces.

Theoretical methods for defect electronic structure

Even simple answers can be useful answers. At one level, electrons and holes can be treated implicitly only. Born's model of ionic solids as *polarizable point ions*, interacting through transferable inter-atomic potentials, was the basis for describing cohesion, dielectric and vibrational properties of perfect solids. The large Coulomb energies are the reason why accurate defect studies were first practical for ionic crystals. Yet polarization energies are large too (for an ion of charge $Z + 2$ substituting for a $2+ \text{Mg}$ ion in MgO , Madelung terms are about $24 \times Z \text{ eV}$ and polarization about $6 \times Z^2 \text{ eV}$) and explain why so many charge states of impurities can be stable. Mott and Littleton's systematic way of calculating the Coulomb and polarization contributions to defect formation energies in ionic solids forms the basis of many current state-of-the-art codes (Hayes and Stoneham, 1985; Stoneham, 1975).

Modelling simple one-electron systems: For non-polar semiconductors, *effective mass theory* is superb, often working well beyond its justification using empirical bulk properties. For ionic crystals, point ions are a surprisingly good start, but *pseudo-potential methods* were necessary to explain why, and to give the "ion-size corrections" needed for accurate trends over the whole series of alkali halides and oxides. The F center (electron at an anion vacancy) was the first deep trap to be predicted well over a very wide range of halide and oxide hosts, and the same techniques were successful in early modelling states of self-trapped excitons.

For most systems, however, the *many-electron treatment* is essential. Here both first-principles and empirical theories are often used. Empirical methods help most in new situations where what is important is still not certain, for more complex systems, where computer power and technique has yet to be sufficient for the best methods, or for extrapolation across a broad range of materials. Many of the problems addressed empirically today will be solved by far better methods tomorrow.

By choosing *first-principles methods* one is not reliant on parametrized theories or fitting possibly inaccurate experiments (Martin, 2004). These theories can be applied more reliably to hypothetical materials, defects for which data are not available, or for extreme temperature, pressure and irradiation conditions. Computational techniques for modelling defects in solids exist in a form of computer codes implementing a *model of a solid with a defect* and *methods* for calculation of defect structure and properties (Freysoldt et al., 2014).

Most first-principles *methods* are based on *Hartree-Fock* and *Density Functional Theory* (DFT) approximations. DFT states that the ground state properties of a system are given by the charge density, and state-of-the-art methods allow us to compute the charge density and energy self-consistently using various effective exchange-correlation potentials that account for the quantum mechanical interactions between electrons. The local density approximation (LDA) takes the exchange-correlation potential from uniform electron gas theory at the density for each point in the material. The generalized gradient approximation (GGA) includes the effects of local gradients in the density. DFT's success is facilitated by the computational efficiency of these approximations, which made it applicable to studies of complex materials and defects. The continuous development of more sophisticated density functionals as well as Quantum Monte Carlo methods significantly improved the accuracy of predicted defect properties. As computing power has increased, hybrid DFT functionals have also been employed, which combine DFT estimation of exchange with a percentage of Hartree-Fock exchange (called "exact" exchange). Hybrid DFT has been successful in predicting band gaps and describing the behavior of localized states.

The main computational *models* of a point defect in a crystal include a periodic model, an embedded cluster, and molecular cluster models, illustrated in Fig. 3. They differ by the boundary conditions imposed on a system wave-function. The *periodic model* was first developed for calculating electronic structure and properties of ideal crystals (Kantorovich, 2004; Kittel, 2004), whereas the cluster model evolved from molecular calculations (Grimes et al., 1992). They are compared in Table 1. Within the periodic model a unit cell with a defect is periodically translated. It is ideal if one is interested in the properties of large concentration of neutral defects, which weakly perturb the surrounding lattice. Many molecular cluster models treat a defect with surrounding atoms simply as a molecule or *cluster*. They disregard the effects of the rest of the atoms outside the cluster, but apply semi-empirical fixes to the atoms at the cluster surface to diminish their adverse effect. This major problem is addressed and partially solved in "embedded

Fig. 3 Schematic of two prevalent computational models used for simulations of defects. (A) A periodic model, where each rectangle represents a periodic cell. (B) An embedded cluster model, where a cluster of atoms in the region I is treated using a high level quantum-mechanical theory (DFT, Coupled Cluster, GW); the surrounding region II is treated on a more approximate level of theory (semi-empirical quantum chemistry, atomistic simulations using a polarizable ion model to treat atomic polarizations); the region III is a polarizable continuum representing the rest of the infinite solid. The boundary between regions I and II is represented by link atoms or embedding potential to provide a seamless link between the two regions.

Table 1 Comparison of computational methods used in defect calculations.

Models	Methods	Properties
<i>Molecular cluster</i> : molecule represents local defect environment in a solid	Density Functional Theory and ab initio and semi-empirical Hartree-Fock Theory in localized basis sets	Can predict local defect structure, vibrational, optical and EPR properties providing intermediate and long-range order are not important.
<i>Embedded cluster</i> : local defect environment is treated quantum-mechanically and the rest of the solid structure treated classically	Density Functional Theory and ab initio and semi-empirical Hartree-Fock Theory in localized basis sets	Can predict local defect structure, ionization energies and electron and hole affinities, vibrational, optical and EPR properties and diffusion parameters. Can treat infinite amorphous structures.
<i>Periodic</i> : defects are repeated periodically in a lattice	Density Functional Theory, Hartree-Fock Theory, tight-binding methods in plane wave and localized basis sets.	Can predict local defect structure, electrical levels, vibrational and EPR properties and diffusion parameters providing the interaction between periodically translated defects is small. Treats amorphous structures as periodic arrangement of disordered cells.

cluster" models, where a cluster with a defect is embedded in an infinite solid (Fig. 3B). This model works well in ionic insulators, such as MgO, however, for insulators with ionic-covalent character of bonding, such as SiO₂ or Ga₂O₃, an accurate embedding is challenging to achieve. It is ideal for modelling individual defects and allows one to self-consistently include the effect of polarizable environment into predicting the defect characteristics, which is particularly important for charged defects in insulators.

Both static Hartree-Fock and DFT methods are ground state theories, in the form of an effective one-particle Schrödinger equation (the Kohn-Sham equation in the case of DFT). The eigenvalues of these equations are often interpreted as electron energies and their differences as optical excitation energies. This interpretation is linked to an intuitive picture of independent electrons occupying well-defined energy levels. However, this is a gross simplification: the electrons are not independent, and when, for example, an electron is removed to form a hole, all remaining electrons respond by changing their electronic states. This electron relaxation and other quantum-mechanical contributions must be taken into account for energy differences to be calculated correctly. This can be achieved using advanced methods of quantum chemistry, such as Coupled Cluster, as well as other techniques often implemented in periodic boundary conditions, such as GW (Golze et al., 2019). The improved efficiency of GW facilitated accurate predictions of electronic excitations in materials and defects as well as of charged excitations as measured in direct or inverse photoemission spectroscopy. One can retain the picture of one-particle energy levels, but these particles are quasi-electrons and quasi-holes, which embody the effects of interaction with all the other particles.

The concept of *quasi-particles* is often used to represent the electronic states of an insulator with a defect schematically, as shown in Fig. 4. Such energy diagrams usually include the highest valence band and the lowest conduction band of the system (Freysoldt et al., 2014). Point defects and impurities may induce occupied and unoccupied states in the gap and so-called resonant states in the valence and conduction bands of the system. The wavefunctions of defect states are often strongly localized in the defect area (Fig. 5) and the corresponding quasi-electron energies are located in the band gap of the solid. The resonant states differ from the ordinary band states in that they are localized in the defect region with the major wavefunction component decaying exponentially from the defect, but their quasi-electron energies are located within the occupied or unoccupied bands. Quasi-particle energy diagrams similar to that shown in Fig. 4 are used to summarize pictorially the electronic structure and processes involving optical excitation, luminescence, ionization and energy transfer between defects.

Coupling of electrons and lattice deformation

One of the issues crucial for the understanding defect properties is how defect electrons couple to the motion of nearby ions or, alternatively, the way defect electrons apply forces to host ions (Hayes and Stoneham, 1985; Itoh and Stoneham, 2001; Song and Williams, 1993; Stoneham, 1975). The static polarization and distortion of the host lattice affects defect formation and transition energies; the dynamics leads to transitions between electronic states and to defect diffusive motion. Optical spectra change qualitatively: the optical line width, the existence of a zero-phonon line, and the Stokes shift, the energy difference between optical absorption and emission energies, give direct measures of this coupling. Although any of a large number of atomic displacements might influence a defect in a solid, often a very specific combination of displacements is especially important. For example, the radial displacement of the nearest neighbors to the defect can be represented by a single *configuration coordinate* Q , as illustrated in Fig. 6. We note that it is most unlikely that the coordinate Q will be one of the dynamically-independent *normal vibrational modes* q . It is almost certain that normal modes of many different frequencies will be needed to make up Q . Moreover, the precise mode combinations making up Q will depend on the defect electronic state (it will be different in the excited state of defects shown in

Fig. 4 The quasi-particle energy diagram representing total energies of a solid with two defects A and B. The defect A produces local single-occupied and unoccupied states within the band gap, and resonant states (denoted RV and RC) in the valence and conduction band, respectively. The defect B is characterized only by two local states in the gap. The arrows 1–4 correspond to optical transitions between states in the defect A. The arrow 5 corresponds to thermal ionization of an electron from the excited state of the defect A into the conduction band. Process 6 is non-radiative trapping of an electron from the conduction band on an empty state of the defect B. Process 7 is the de-excitation of the defect B which may be either radiative or non-radiative.

Fig. 5 The geometric configurations and electronic states of positively charged oxygen vacancies in oxides. (A) The relaxed configuration of the positively charged oxygen vacancy, E'_1 center, in α -quartz; red are oxygen ions. The envelope of the density of the unpaired electron mostly localized on a p-orbital of one Si ion is shown pointing into the vacancy. The arrow indicates the direction of the displacement of the second Si ion of the vacancy. This is the so-called "puckered" configuration of the E'_1 center. (B) The relaxed configuration of the positively charged oxygen vacancy, F^+ center, in MgO; red are oxygen ions. The envelope of the density of the unpaired electron localized on an s-orbital inside the vacancy is shown. Note the electron density of the unpaired electron propagates much further out from the vacancy. Depressions in the envelope show that the unpaired electron avoids the core electrons of surrounding Mg ions. The arrows indicate the symmetric displacements of the six nearest-neighbor Mg ions surrounding the vacancy. This radial displacement of the six Mg ions is often used as a configuration coordinate, Q , in considering the spectroscopic properties of the F^+ center.

Fig. 6 Configuration coordinate diagram. The figure shows the main characteristic energies and transitions, both radiative and non-radiative. Accepting coordinate represents one of the configuration coordinates effective in vibrational energy dissipation. The vertical arrow A – B corresponds to a vertical (so called Franck-Condon) transition between the ground and excited states of the system represented by two harmonic energy surfaces. Horizontal lines indicate vibrational energy levels with small arrows showing transitions between these levels (cooling transitions) dissipating the excess vibrational energy (relaxation energy). The transition C – D between the lowest vibrational state in the excited state back to the ground state energy surface corresponds to the Franck-Condon de-excitation with photon emission (luminescence or phosphorescence). It is accompanied by further cooling transitions in ground electronic state. The area near the crossing point X is where the system can cross nonradiatively from the excited to the ground state. In this case the relaxation energy, which is the energy difference between X and A or between C and A, is dissipated into lattice vibrations. The zero-phonon transition energy is the energy difference between C and A.

Fig. 4). Yet this configuration coordinate model is surprisingly effective, giving an invaluable tool for showing what happens after electronic excitation, and a simple language for describing defect processes. An example of such a diagram is given in Fig. 6.

A central issue for optical and electronic materials is how they recover after excitation. A good X-ray phosphor emits the most visible light after excitation and degrades least from defect production. A solid-state laser needs both population inversion and a lack of wasteful competing processes; carrier capture in semiconductors determines what defects and materials are acceptable; photographic (not to mention the photosynthetic) processes have their own demands. In such cases, non-radiative transitions are central, a role evident from over half a century of theory.

In *nonradiative decay*, excitation energy is transformed into heat, defect production, or to excitation of other electrons, the so-called Auger processes which are especially important at higher carrier densities. The recombination of carriers in semiconductors and insulators is governed mainly by nonradiative processes often described by the Shockley-Read-Hall model. The probability of this process decreases when the number of the emitted phonons increases. Therefore, recombination is facilitated by the presence of

deep impurity or other defect states (recombination centers), because this makes it possible to reduce the number of phonons emitted in one event. Hence, the rate of recombination is governed by the nature and concentration of recombination centers in a crystal. For deep centers, the nonradiative carrier capture occurs via multiphonon emission. Another common manifestation of nonradiative decay of an excited state concerns suppression of luminescence. Can one tell from optical absorption data alone whether or not luminescence will occur? Huang and Rhys's (1950) seminal study showed one possible criterion: the larger the excitation energy, the faster the optical transition and the slower the non-radiative decay, since larger numbers of phonons would be needed (see Fig. 6). Dexter et al. (1956) developed other criteria relating to the final state energy achieved by optical excitation and the energy at which the ground and excited electronic states intersected on the configuration coordinate diagram: the energy surfaces, rather than some matrix element, controlled the result. This led Bartram & Stoneham to show that simple expressions could be given for branching ratios at critical steps, and that these ideas - which could be applied to much more complex cases - correctly predicted behavior over a wide range of systems.

Self-trapping and localization

Landau made the remarkable suggestion of *self-trapping*: an electron could be so strongly coupled to the lattice that, even without a defect, it would lead to lattice distortion and be effectively immobilized. The suggestion was the basis of the important ideas of small polarons (incoherent hopping of localized carriers, as in some transition metal oxides, rather than the long mean-free-path motion of carriers in Si or metals), and even of the recently-observed barrier to self-trapping (Itoh and Stoneham, 2001; Song and Williams, 1993). The observed small polarons (e.g. self-trapped holes in halides in Fig. 7) show both the soundness of Landau's idea and (since naive belief in band theory appears to be violated) the importance of theorists learning from experiment too. Hole polarons are ubiquitous in oxides and halides, but electron polarons are less common. If a polaron can trap two electrons (or holes) with the second bound more strongly than the first, it has *negative-U* properties (where pairing of two electrons and two holes in a localized region is favored against single polaron formation), as originally suggested by Anderson (1975). Distortion and polarization dominate too in negative-U behavior of defects, where a charge disproportionation is exothermic (so the

Fig. 7 Atomic structure of the trapped hole centers in halides and MgO: (A) AgCl – the hole is localized on a silver ion; (B) alkali halides of NaCl structure – the hole is localized on two halogen ions forming a Cl_2 molecule; (C) CaF_2 – the hole is localized on two fluorine ions forming a F_2 molecule. Note that in (B) – (C) the X_2^- ($\text{X} = \text{F}, \text{Cl}$) molecular ion occupies two nearest anion lattice sites. (D) The hole localized on an O^- ion neighboring the Mg vacancy (V_{Mg}) in MgO (the so-called V^- center). In all cases, the hole localization is accompanied by a strong distortion of the surrounding lattice (not shown in the figure).

positive vacancies in Si decay from $2 V^+$ to $V^0 + V^{2+}$ as well as H^+ and H^- are the preferred thermodynamic states of hydrogen in the bulk of many oxides).

Localization can correspond to carrier or exciton trapping by an isolated defect (*extrinsic trapping*). If there is an attractive perturbation ΔV at a defect site, then, for large enough ΔV , a bound state emerges for the extra electron, hole or exciton. Both impurity-induced potentials and electron-phonon interaction play crucial roles in this localization. Extrinsic electron trapping near defects is quite rare in insulators because electron polarons are not easily formed in these materials. However, exciton trapping by impurities is very common in most insulators.

As well-established examples of extrinsic hole trapping, one can consider holes trapped near cation vacancies in MgO (so called V° and V^- centers) and holes trapped near Ge and Al impurities in α -quartz (Schirmer, 2006). In particular, cation vacancies in MgO have an effective negative charge of $-2e$ with respect to the lattice and therefore attract positive holes. When one hole is trapped, a paramagnetic V^- center is formed, well-studied experimentally using Electron Paramagnetic Resonance and optical spectroscopy (Fig. 7D). Similar centers occur in CaO, SrO and BaO, in the fourfold coordinated oxides like BeO and ZnO and in related sulfides, selenides and tellurides. In MgO, at low temperatures the hole is strongly localized on one of the six oxygen ions surrounding the vacancy. As the temperature rises, the hole moves more and more rapidly among the equivalent oxygens until it appears delocalized at room temperature. The nature of optical transitions in this center is characteristic to many other hole centers in oxides: there are two types of optical transitions. One is internal to the O^- ion on which the hole is localized. This is a crystal-field transition, since the transition energy is largely determined by the electrical field at the O^- ion due to the Mg^{2+} vacancy. The other, more important, transitions involve charge transfer of the hole to other neighbors of the vacancy. These are analogous to electron excitation from resonant states in the valence band into the unoccupied hole state shown in Fig. 4. Similar charge transfers are important in determining the color of gemstones.

Extensive experimental and theoretical studies show that excitons self-trap in both α -quartz (the most stable crystalline polymorph of SiO_2) and amorphous SiO_2 . However, EPR studies show that holes and electrons do not self-trap in α -quartz. Yet, in high-purity Ge-doped quartz, low-temperature irradiation leads to the formation of a hole center localised at an oxygen site next to Ge. This formation of the localized hole centers associated with Ge impurity can be described as “extrinsic self-trapping,” where both impurity-induced potential and electron-phonon interaction play crucial roles in the hole localization. In amorphous SiO_2 , two types of localized hole centers have been determined that are free from pre-existing lattice defects such as vacancies, interstitials, or impurities, and are trapped by some precursor states induced by *disorder* of amorphous structure. This example demonstrates that the mechanisms of localization processes in amorphous solids are more complicated than in crystalline materials due to co-existence of electron-phonon interaction, structural defects and static potential fluctuations. It is not straightforward to distinguish experimentally the polaron self-trapping due to strong electron-phonon interaction from charge trapping by structural defects in amorphous structure.

Defects in disordered materials

Defect structures and processes in amorphous materials have been studied extensively, partly as fundamental research on model amorphous materials, and partly to understand their extremely important role in technology (Catlow, 1994; Mott and Davis, 1979; Pacchioni et al., 2000). For example, the mechanisms and kinetics of relaxation of electronic excitations in SiO_2 are crucial in micro- and opto-electronics applications (Pacchioni et al., 2000). There are at least four basic fallacies concerning amorphous systems. First, it is wrong to assume there is only a single amorphous structure for a given composition, since the method of preparation can have significant effects. Secondly, it is wrong to think that the *mean* energies of defect formation or of trap ionization in an amorphous structure are sufficient to understand the behavior: the form and tails of the distribution are equally important. Thirdly, one should not assume that crystals and amorphous systems of the same composition have the same values for defect and trap energies. Finally, amorphous systems may have several accessible metastable states, leading to easy reorganization of the structure when the system is perturbed by defect processes, such as carrier trapping and detrapping.

Structural disorder in amorphous materials generally means that all sites are different. In most experimental studies the effect is hidden in broadening of the spectral features and only rarely has disorder been implicated in formation of different structural types of the same defect. Predicting defect properties and relative abundance of different defect configurations generally requires considering not one or several, as in crystals, but a statistical ensemble of structural sites. Additional factors include the sample history and the mechanism of defect formation. This provides new challenges for both theoretical and experimental analysis of defects in amorphous materials.

Surfaces and interfaces

No discussion of defects could be complete without mention of interfaces. Their structures are rarely, if ever, the ideal terminations of perfect crystal structures, and the variety of reconstructions is becoming clearer as microscopies (e.g. the *Transmission Electron Microscope*, *Scanning Tunnelling Microscope* and *Atomic Force Microscope*) develop (Carter and Williams, 2016; Hofer et al., 2003). Defects or impurities at surfaces and interfaces are especially important for most applications. It is impurities close to grain boundaries, which are most strongly involved in the operation of solid-state gas sensors, and the framework of Debye-Hückel

theory is central (Maier, 2004). The *space-charge* in silver halides relates to their photographic effectiveness; the Mott and Gurney theory provided the basic framework. Space-charge layers play significant role in the overall performance of electrochemical cells and ionic conduction. Defects at the interface between silicon and gate dielectrics control the reliability of microelectronic devices. Ceramists recognize the importance of segregation in oxides, where experiment shows Mg in alumina gives dramatic improvements in sintering.

Defects also influence adhesion. What controls the variation from one oxide to another of the adhesion of a non-reactive metal? Why (a related question) does liquid Cu wet some oxides (NiO, urania, chromia) but not other similar oxides (MgO, thoria, alumina)? The answer lies largely in the defect populations and basic electrostatics: charged defects close to the highly-polarizable metal have lower energy; those close to the unpolarizable vacuum have higher energy. The operation of gas sensors relies on electron transfer across interfaces, as does the operation of contacts to semiconductors (whether conventional or organic) and electrodes.

Yet another issue, specific for microelectronics applications, is that the dielectric of interest can be in contact with the electrode(s) - semiconducting (e.g. silicon) or metallic - which provides a source of extra electrons. Also, a dielectric film can be placed in the electric field between the two electrodes, which may alter the defect charge states. Charged defects can cause substantial random fields, which may alter breakdown thresholds locally. Typically, for 100 ppm of charged defects, there will be random fields of order 10^5 V/cm. Defects can be involved in stress-induced leakage currents (SILC) and *dielectric breakdown*. In such cases, the defect offers a channel for electron transfer across the dielectric: an electron tunnels from one electrode into an oxide defect; there are then relaxation processes or a sequence of defect processes, and the electron can then tunnel to the other electrode (Fleetwood et al., 2009). What can we say about the defects responsible, their electrical energy levels and relaxation energies (differences in energy for electron capture and emission)? Can we give useful estimates of electron and hole trapping cross-sections? Will there be any field-stimulated diffusion of defects?

To define which charge state of an intrinsic defect (e.g. vacancy) or incorporated defect species is favored, assuming the common case of oxide film grown on silicon, the source or sink of electrons is the bottom of silicon conduction band at the Si/SiO₂ interface. Hence the *chemical potential* of the electron can be chosen at the bottom of Si conduction band or at the silicon midgap energy. Electrons are assumed to be able to tunnel elastically or inelastically from/to these states to/from defect states in the oxide and create charged species as illustrated in Fig. 8. Most calculations use experimental information to estimate the energy of an electron at the bottom of the conduction band of Si with respect to the defect states.

Fig. 8 Potential energy diagrams of an electronic device with a defect. (A) Illustrates an elastic tunnelling of an electron from the bottom of the conduction band of the left electrode (Si, Ge) into the gate metal electrode; electron scatters on the oxide trap. (B) Inelastic tunnelling of an electron from the bottom of the conduction band of the left electrode (Si, Ge) into the gate metal electrode. The electron first tunnels into the localized state of the oxide trap and, after vibrational relaxation, tunnels into the metal electrode. This type of process is also called multi-phonon trap assisted tunnelling. (C) Diagram showing the formation energies of O vacancies in the monoclinic phase of HfO₂ as a function of the Fermi level position (electron chemical potential) in the band gap calculated using DFT in a periodic model. Lines show the dependence of the defect formation energy in different charge states on the electron chemical potential. Crossing points are the charge transition energies. They correspond to chemical potential above/below which the existence of the defect in the different charge state is becoming more energetically favorable. One can see that positively charged vacancy states dominate up to about 4.3 eV.

The key point about defect states in dielectrics from a device point of view is to control the dependence of the defect charge state on the position of the system Fermi energy (Fleetwood et al., 2009; Freysoldt et al., 2014). It is useful to distinguish two charge transition levels: the thermodynamic level, E_{th} , and the transient level, E_{tr} . The thermodynamic charge transition level corresponds to the system Fermi energy for which a defect changes its charge in thermal equilibrium. E_{th} is defined as a difference of total energies of systems of N and $N + 1$ electrons, each in its fully relaxed ground state: $E_{th} = E(N + 1) - E(N)$. Thus, if E_F is the energy required to remove an electron from some electron reservoir (e.g. Si at the Si/SiO₂ interface), $E_{th} - E_F$ is the energy required to add an electron from the reservoir to the lowest unoccupied charge-state level. The position of the defect charge transition levels indicates whether the defect is a deep or shallow donor or an acceptor. Furthermore, if the defect charge transition level is in the same position as the electrode Fermi level (said to be in resonance), then tunnelling rates between the defect and electrode will be very high, provided the defect is close enough to the interface (typically up to 3 nm). An example of defect formation energy diagram showing charge transition levels is shown in Fig. 8C.

Taking into account that the electrical measurements and the electronic processes are often fast compared with the time needed for the system to come to equilibrium, another, transient, level is introduced, which is consistent with the Frank-Condon principle. E_{tr} is defined as the energy required for trapping an electron or a hole in the geometry of the system as it was prior to the trapping. Thus E_{tr} are obtained as the differences of the total energies of the system with N and $N + 1$ electron, but in the local atomic geometries, which correspond to one of these systems. For example, $E_{tr}(0/-) = E(-) - E(0)$ denotes the energy required to add an electron to the neutral defect calculated using the neutral defect geometry.

Once the charge-transition levels are calculated, the dependence of the defect charge state on the electrode Fermi energy can be introduced via a correction term $q \times E_F$, where E_F is varied in the energy range from the maximum of the last valence band of the oxide to the bottom of the first conduction band. The results are presented as plots of E_{th} vs. E_F or E_{tr} vs. E_F calculated for different values of E_F (Fig. 8C). The crossing points of the corresponding lines determine the regions where one charge state of a defect is more favorable than the other. Although the Fermi energy remains unknown in the experiment, such diagrams allow one to identify some critical cases and help in the analysis of the experimental data. The same approach is used to determine the dependence of the defect formation energies on the position of the Fermi energy.

Conclusion

Our understanding of point defects in insulators has progressed enormously since the pioneering works of Frenkel and Schottky. Advances in experimental defect characterization combined with increasing accuracy of theoretical calculations of defect properties and reactions provide defect models of increasingly complex processes in the bulk and at surfaces of insulators. Transitioning from understanding fundamental materials behavior to development of quantitative approaches to explain and predict experimental observations requires further advances in the computational methods that take advantage of the increasingly powerful computing hardware. Material function is, however, multi-scale and is intimately linked not only to point defects considered here but also to microstructural processes (diffusion, electron transfer, chemical reactions) at the internal grain boundaries and interfaces to electrodes or contacts between insulators and other materials. The roles of microstructure of materials (particularly texture) are well established in metallurgy, but much less understood in insulators, e.g. functional ceramics, particularly when it comes to linking the atomic structure of polycrystalline materials to their function. The challenge is to merge this information at various length scales and to develop a fundamental understanding of the evolution of the microstructure and its effect on properties, such as thermal-mechanical response, electrical response, degradation, and failure. A step-change will be achieved when it is possible to predict the effect of changing the microstructure on system function and so guide the materials synthesis and processing.

Abstract

Density functional theory (DFT) is an essential building block for modern theoretical physics, chemistry, and engineering, especially those concerning electronic properties. Through decades of development, various program packages for first-principles electronic structure calculation are now available. Their sophisticated interfaces allow users to apply DFT to actual systems, even without knowing the theory. It is hence becoming more and more important to recall the fundamentals of how DFT enables accurate calculations. This article attempts to provide such knowledge with a minimal overview of DFT—its basic foundation, relations to observable electronic and nuclear dynamical properties, and some of its cutting-edge applications.

Key points

- Theoretical foundation of density functional theory is reviewed.
- Relations to experimentally observable quantities are highlighted.
- Modern applications of density functional theory are introduced.

Introduction

The motion of the electrons in atoms, molecules, and solids is described by the Schrödinger (or Dirac) equation. The computational complexity to obtain the exact solution grows exponentially with the number of electrons N . Calculating exact ground-state wave function is prohibitively expensive when N is more than a few dozen. Therefore, it has been a great challenge to develop a powerful and accurate numerical method to calculate electronic structures.

[☆]*Change History:* November 2022. Y Nomura and R Akashi updated Sections: “Introduction” “Born-Oppenheimer Approximation” “Hohenberg-Kohn theorem and Kohn-Sham equation” “Extensions” “LDA, GGA, and orbital dependent functionals” “Single-particle spectrum” “Kohn-Sham states in practice” “Nuclear dynamics”.

There are mainly two numerical approaches. One is the wave function theory. It directly deals with the many-body wave function itself and attempts to find good approximations to the exact wave function. The other is the density functional theory (DFT), for which we will give a brief review. By employing the electron density $\rho(\mathbf{r})$ (a function of three coordinate variables) as the fundamental variable instead of the many-body wave function (a function of $3N$ coordinate variables), DFT has drastically reduced the computational cost. Therefore, DFT is the most widely used method for electronic structure calculations of solids.

Here, we briefly review the fundamental and practical aspects of DFT. Section “Basic formalism” reviews the Hohenberg-Kohn theorem and the Kohn-Sham equation, which gives a foundation of DFT. We also describe several extensions of DFT. In DFT, as described below, the exchange-correlation functional is one of the most fundamental quantities. Section “Approximate exchange-correlation functionals” is devoted to a discussion of approximations to the exchange-correlation functional. Section “Electronic structure” presents several topics related to electronic structure calculations. In Section “Nuclear dynamics,” we show that DFT can also be used to calculate the properties of atomic vibrations. Section “Practical guide” provides a practical guide of DFT. Finally, we give a summary in Section “Summary.”

Basic formalism

We start from the full non-relativistic Hamiltonian, in which electrons and atomic nuclei interact with each other. Because the masses of nuclei are much heavier than that of electrons, the kinetic energies of nuclei are usually much smaller than that of electrons. Then, to a good approximation, we can treat electron and nuclear dynamics separately. DFT is a theory for dealing with the electronic part under this approximation. In this section, we first briefly discuss the Born-Oppenheimer approximation (Born and Oppenheimer, 1927), which is the most widely used framework to derive separate equations for the electron and nuclear dynamics. Then, we discuss the Hohenberg-Kohn theorem (Hohenberg and Kohn, 1964) and the Kohn-Sham equation (Kohn and Sham, 1965), which form the basis of DFT.

Born-Oppenheimer approximation

The Hamiltonian for interacting electrons and nuclei reads

$$\widehat{\mathcal{H}} = -\sum_I \frac{\hbar^2}{2M_I} \frac{\partial^2}{\partial \mathbf{R}_I^2} - \sum_i \frac{\hbar^2}{2m} \frac{\partial^2}{\partial \mathbf{r}_i^2} + V(\{\mathbf{r}\}, \{\mathbf{R}\}), \quad (1)$$

where

$$V(\{\mathbf{r}\}, \{\mathbf{R}\}) = \sum_{i<j} \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} - \sum_{i,I} \frac{Z_I e^2}{|\mathbf{r}_i - \mathbf{R}_I|} + \sum_{I<J} \frac{Z_I Z_J e^2}{|\mathbf{R}_I - \mathbf{R}_J|}$$

with $\{\mathbf{r}\}$ and $\{\mathbf{R}\}$ being the set of electron and nucleus coordinates, respectively, and i and I labeling electrons and nuclei. The Born-Oppenheimer approximation makes use of the large difference in the mass between the nuclei and electrons. Within this approximation, the electron and nuclear motions are treated separately, and the wave function of electrons and nuclei is given by a product of the electron part Ψ_e and the nuclear part Φ_n . In the following, we briefly describe the equations obtained from the Born-Oppenheimer approximation.

If we neglect the nuclear kinetic energy, which is much smaller than that of electrons, from the Hamiltonian, we obtain the electron Schrödinger equation:

$$\left[-\sum_i \frac{\hbar^2}{2m} \frac{\partial^2}{\partial \mathbf{r}_i^2} + V(\{\mathbf{r}\}, \{\mathbf{R}\}) \right] \Psi_e(\{\mathbf{r}\}|\{\mathbf{R}\}) = E(\{\mathbf{R}\}) \Psi_e(\{\mathbf{r}\}|\{\mathbf{R}\}). \quad (2)$$

Here, the equation is solved for fixed nuclear positions. The nuclear dynamics with a smaller energy scale are treated separately from the electron dynamics. The Schrödinger equation for the nuclear part is given by

$$\left[-\sum_I \frac{\hbar^2}{2M_I} \frac{\partial^2}{\partial \mathbf{R}_I^2} + E(\{\mathbf{R}\}) \right] \Phi_n(\{\mathbf{R}\}) = \varepsilon \Phi_n(\{\mathbf{R}\}), \quad (3)$$

where the total energy of the electron part $E(\{\mathbf{R}\})$ serves as a potential for the nuclear dynamics (Born-Oppenheimer energy surface). ε is the total energy of the electron-nucleus coupled system. In the following, we explain the idea of DFT for solving the electronic part (Eq. 2). We also discuss the nuclear dynamics in Section “Nuclear dynamics.”

Hohenberg-Kohn theorem and Kohn-Sham equation

The electronic part of the Hamiltonian is given by

$$\widehat{\mathcal{H}}_e = \sum_i \left(-\frac{\hbar^2}{2m} \frac{\partial^2}{\partial \mathbf{r}_i^2} - \sum_I \frac{Z_I e^2}{|\mathbf{r}_i - \mathbf{R}_I|} \right) + \sum_{i<j} \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (4)$$

As is mentioned in Section “Introduction,” when the number of electrons is more than a few dozen, it is prohibitively demanding to obtain the exact ground-state wave function.

In DFT, the electron density $\rho(\mathbf{r})$ is used as the fundamental variable instead of the many-body wave function. The electron density is much more tractable than the many-body wave function because it depends on only three coordinate variables, regardless of the number of electrons. This approach has been justified by the Hohenberg-Kohn theorem.

The theorem first states one-to-one correspondence between the ground-state electron density and the external potential. Therefore, once the ground-state electron density is known, the external potential is determined uniquely. Then, in principle, physical properties associated with the ground-state wave function are unambiguously determined by the electron density. In particular, the kinetic and electron-electron interaction energies of the ground state can be expressed as universal functionals of the electron density ($E_{\text{kin}}[\rho]$ and $E_{\text{ee}}[\rho]$, respectively). The term “universal” indicates that the forms of the functionals do not depend explicitly on the nuclear positions.

The theorem also gives a variational principle. When we define the energy functional

$$E_v[\rho] = E_{\text{kin}}[\rho] + \int \rho(\mathbf{r})v(\mathbf{r})d\mathbf{r} + E_{\text{ee}}[\rho] \quad (5)$$

for some external potential $v(\mathbf{r})$, the functional satisfies the inequality

$$E_v[\rho] \geq E_v[\rho_0] = E_0, \quad (6)$$

where $\rho_0(E_0)$ is the ground-state electron density (energy) under the potential $v(\mathbf{r})$, respectively. Therefore, the ground-state electron density can be obtained by searching for the electron density that minimizes the energy functional $E_v[\rho]$.

Although the variational principle in Eq. (6) looks simple, the major problem is that the exact forms of the functionals, $E_{\text{kin}}[\rho]$ and $E_{\text{ee}}[\rho]$, are unknown. For this problem, Kohn and Sham have proposed an idea of introducing “orbitals” to approximate the kinetic energy functional $E_{\text{kin}}[\rho]$. This has opened up a way to perform DFT calculations with sufficient accuracy for practical use. Therefore, most of the modern DFT implementations employ the Kohn-Sham scheme; thus, we discuss this scheme in more detail below. As for the direct variational approach (orbital-free DFT), which is less accurate than the Kohn-Sham approach but has the advantage of being much faster, the current research focus is to construct accurate kinetic energy functionals. One strategy is to reproduce the Kohn-Sham kinetic energy as accurately as possible.

The Kohn-Sham scheme introduces an auxiliary non-interacting system that is designed to give the same electron density as that of the interacting system. The non-interacting system is described by single-particle Schrödinger equation (so called Kohn-Sham equation):

$$\left[-\frac{\hbar^2}{2m} \frac{\partial^2}{\partial \mathbf{r}^2} + v_{\text{eff}}(\mathbf{r}) \right] \phi_i(\mathbf{r}) = \varepsilon_i \phi_i(\mathbf{r}), \quad (7)$$

where $v_{\text{eff}}(\mathbf{r})$ is an effective potential which is determined by Eq. (12), ϕ_i is the Kohn-Sham state, and ε_i is the Kohn-Sham energy eigenvalue. The electron density is given by

$$\rho(\mathbf{r}) = \sum_{i=1}^{\text{occ}} |\phi_i(\mathbf{r})|^2, \quad (8)$$

where the summation runs over occupied Kohn-Sham states.

In the Kohn-Sham scheme, to reproduce the true electron density with Eq. (8), the effective potential $v_{\text{eff}}(\mathbf{r})$ is determined as follows: We first introduce the kinetic energy functional

$$E_{\text{kin}}^{\text{KS}}[\rho] = \sum_{i=1}^{\text{occ}} \int \phi_i^*(\mathbf{r}) \left(-\frac{\hbar^2}{2m} \frac{\partial^2}{\partial \mathbf{r}^2} \right) \phi_i(\mathbf{r}) d\mathbf{r} \quad (9)$$

and the Hartree energy functional

$$E_H[\rho] = \frac{e^2}{2} \iint \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r}d\mathbf{r}'. \quad (10)$$

of the Kohn-Sham system. Next, we introduce so called exchange-correlation functional, whose definition is given by the sum of corrections to the exact kinetic and electron-electron interaction energies of the original interacting system:

$$E_{\text{XC}}[\rho] = (E_{\text{kin}}[\rho] - E_{\text{kin}}^{\text{KS}}[\rho]) + (E_{\text{ee}}[\rho] - E_H[\rho]). \quad (11)$$

Then, one can show that $v_{\text{eff}}(\mathbf{r})$ should be given by

$$v_{\text{eff}}(\mathbf{r}) = v(\mathbf{r}) + e^2 \int \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r}' + v_{\text{XC}}(\mathbf{r}), \quad (12)$$

$$v_{\text{XC}}(\mathbf{r}) = \frac{\delta E_{\text{XC}}[\rho]}{\delta \rho(\mathbf{r})}. \quad (13)$$

One can see that Eqs. (7), (8), and (12) form self-consistent equations. Therefore, in practical DFT calculations based on the Kohn-Sham scheme, the self-consistent equations are solved iteratively with some approximate form of the exchange-correlation functional (see Section “Approximate exchange-correlation functionals” for the detail).

Extensions

The ground states are sometimes not sufficiently characterized only by the charge density distribution. This occurs when any quantities, generally represented by the 1-reduced density matrix, are involved

$$\rho_{\sigma\sigma'}^{(1)}(\mathbf{r}, \mathbf{r}') = \langle \hat{\psi}_{\sigma}^{\dagger}(\mathbf{r}) \hat{\psi}_{\sigma'}(\mathbf{r}') \rangle. \quad (14)$$

$\langle \hat{\mathcal{O}} \rangle$ denotes the expectation value of the operator $\hat{\mathcal{O}}$. $\hat{\psi}_{\sigma}^{\dagger}(\mathbf{r})$ and $\hat{\psi}_{\sigma}(\mathbf{r})$ are the electron creation and annihilation operators in the Fock space, respectively. When the system is subjected to external fields or exhibits spontaneous symmetry breaking, its non-trivial components, such as spin density $\mathbf{m}(\mathbf{r}) = \sum_{\sigma\sigma'} \boldsymbol{\sigma}_{\sigma\sigma'} \rho_{\sigma\sigma'}^{(1)}(\mathbf{r}, \mathbf{r})$ [$\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$], may become nonzero. The framework of DFT can be extended for such situations. Namely, we can introduce $\rho_{\sigma\sigma'}^{(1)}(\mathbf{r})$ as fundamental variables in addition to the charge density distribution $\rho(\mathbf{r})$. A parallelism to the Hohenberg-Kohn theorem holds: The ground state is unambiguously characterized by $\rho(\mathbf{r})$ and combination of $\rho_{\sigma\sigma'}^{(1)}(\mathbf{r})$. The Kohn-Sham equation, which reproduces the identical ρ and $\rho^{(1)}$ in the interacting system, can be constructed with complementary exchange-correlation potentials $v_{\text{XC}}^{\sigma\sigma'}(\mathbf{r}, \mathbf{r}') = \delta E_{\text{XC}}[\rho, \rho^{(1)}] / \delta \rho_{\sigma\sigma'}^{(1)}(\mathbf{r}, \mathbf{r}')$. Such an extension has been first accomplished for the spin density (von Barth and Hedin, 1972). Calculations based on the spin DFT is now widely in practice for describing the electron spin distribution of materials. More generally, the 1-reduced density matrix functional theory has also been developed, which treats all the $\rho_{\sigma\sigma'}^{(1)}(\mathbf{r})$ components as additional variables.

The DFT framework is further extended for degrees of freedom other than the electronic charge and spin. Here we list some representative examples. In the current density functional theory, the current density $\mathbf{j}(\mathbf{r}) = \frac{-e\hbar}{2mi} \sum_{\sigma} \langle [\hat{\psi}_{\sigma}^{\dagger}(\mathbf{r}) \nabla \hat{\psi}_{\sigma}(\mathbf{r}) - [\nabla \hat{\psi}_{\sigma}^{\dagger}(\mathbf{r})] \hat{\psi}_{\sigma}(\mathbf{r})] \rangle$ is treated as a variable. Inclusion of the off-diagonal order variable $\chi_{\sigma\sigma'}(\mathbf{r}, \mathbf{r}') = \langle \hat{\psi}_{\sigma}(\mathbf{r}) \hat{\psi}_{\sigma'}^{\dagger}(\mathbf{r}') \rangle$ has been addressed to deal with superconductivity. It is even possible to invent a DFT with a distribution of nuclear sites $\Gamma(\mathbf{R}_1, \mathbf{R}_2, \dots)$ (treated as points in the Born-Oppenheimer approximation) as an additional variable, which is named multi-component DFT. Interestingly, by combined use of $\chi_{\sigma\sigma'}(\mathbf{r}, \mathbf{r}')$ and $\Gamma(\mathbf{R}_1, \mathbf{R}_2, \dots)$ and extension to nonzero temperature, the phonon-mediated superconductivity is consistently described within the DFT framework, which is called DFT for superconductors.

The concept of introducing a non-interacting reference system that reproduces the charge density of the interacting system can also be extended to the time dependent problem. Suppose the system is described by the time-dependent Schrodinger equation

$$i\hbar \frac{\partial}{\partial t} |\Psi_e(t)\rangle = \hat{\mathcal{H}}_e(t) |\Psi_e(t)\rangle \quad (15)$$

with $\hat{\mathcal{H}}_e(t)$ including a time-dependent external field $v(\mathbf{r}, t)$. The Runge-Gross theorem states that, with a given initial state $|\Psi_e(t_0)\rangle$, a one-to-one correspondence between the time dependent charge density $\rho(\mathbf{r}, t)$ and external potential $v(\mathbf{r}, t)$ holds (Runge and Gross, 1984). With this theorem, the time-dependent density functional theory has been established. Here, one can recast the original system to a non-interacting system

$$i\hbar \frac{\partial}{\partial t} \phi_i(\mathbf{r}, t) = \left[-\frac{\hbar^2}{2m} \frac{\partial^2}{\partial \mathbf{r}^2} + v_{\text{eff}}(\mathbf{r}, t) \right] \phi_i(\mathbf{r}, t). \quad (16)$$

This time-dependent Kohn-Sham equation has been used to simulate ionization and excitation dynamics of atoms, molecules, and solids.

For further reading of the present topics, see, e.g., Parr and Yang (1995), Engel and Dreizler (2010), Lüders et al. (2005), and Marques et al. (2005).

Approximate exchange-correlation functionals

Several exact formulas of the exchange-correlation energy E_{XC} are actually known. But such formulas are not useful because they involve the exact solution of the many-body Schrödinger equation. Practically, we design calculable approximate forms as explicit functionals of ρ so that they comply with correct asymptotes, and apply them to general systems. Here we look over standard approximations in use.

LDA, GGA, and orbital dependent functionals

The concept of gradient expansion gives us a useful strategy for developing the approximate functional forms. In extended systems like periodic solids, nearly uniform itinerant electrons are expected to dominate the electronic properties, and its spatial variation would be treated as a perturbation. Along this line, the accuracy of the approximate forms may be improved systematically.

The exchange-correlation energy density ε_{XC} is introduced by the following decomposition

$$E_{\text{XC}} = \int d\mathbf{r} \rho(\mathbf{r}) \varepsilon_{\text{XC}}(\mathbf{r}). \quad (17)$$

Here, ε_{xc} is in principle a functional of the entire distribution of $\rho(\mathbf{r})$. A systematic approximation is implemented by expressing the spatial dependence of ρ in terms of the local values (semilocal approximation)

$$\varepsilon_{xc}[\rho](\mathbf{r}) = \varepsilon_{xc}(\rho(\mathbf{r}), \nabla\rho(\mathbf{r}), \dots). \quad (18)$$

The first approximate form is the local density approximation (LDA)

$$\varepsilon_{xc}[\rho](\mathbf{r}) \simeq \varepsilon_{xc}(\rho(\mathbf{r})). \quad (19)$$

This form becomes exact in the uniform electron gas, where $\rho(\mathbf{r})$ is constant in space. Useful approximate models within the LDA can be derived from accurate calculations for uniform electron gas by sophisticated wavefunction methods such as the diffusion Monte Carlo method. The parameters in the models are determined by fitting the reference numerical data of $\varepsilon_{xc}(\rho_{\text{uni}})$ as functions of the uniform density ρ_{uni} . Such models, being accurate for the uniform systems, are applied to non-uniform systems with Eq. (19).

The approximation can be improved by taking into account the higher order derivatives. The generalized gradient approximation (GGA) incorporates the first-order derivative of ρ

$$\varepsilon_{xc}[\rho](\mathbf{r}) \simeq \varepsilon_{xc}(\rho(\mathbf{r}), \nabla\rho(\mathbf{r})). \quad (20)$$

The meta-GGA incorporates the Laplacian of ρ , as well as kinetic energy density $\tau(\mathbf{r}) = \sum_i |\nabla\phi_i(\mathbf{r})|^2$

$$\varepsilon_{xc}[\rho](\mathbf{r}) \simeq \varepsilon_{xc}(\rho(\mathbf{r}), \nabla\rho(\mathbf{r}), \Delta\rho(\mathbf{r}), \tau(\mathbf{r})). \quad (21)$$

A common strategy for implementing the practical forms for those approximations is as follows: (i) derive asymptotic behavior of the exact functional in extreme cases, (ii) design an analytic model so that those asymptotes are reproduced, and (iii) determine the remaining model parameters, referring to some “norm” systems or any principle like maximal smoothness.

Adding the higher-order gradients may not be efficient for incorporating quantum effects such as the Pauli exclusion and dynamical/static correlations. To describe such effects, the Kohn-Sham orbitals, which are also implicit functionals of ρ , are explicitly included as variables.

For the former, the exact exchange term (EXX)

$$E^{\text{EXX}} = -\frac{e^2}{2} \sum_{ij}^{\text{occ}} \iint d\mathbf{r} d\mathbf{r}' \phi_i^*(\mathbf{r}) \phi_j^*(\mathbf{r}') \frac{1}{|\mathbf{r} - \mathbf{r}'|} \phi_i(\mathbf{r}') \phi_j(\mathbf{r})$$

is added to E_{xc} instead of the exchange part of the functional. The magnitude of the E^{EXX} term is tuned by a prefactor and/or cutoff for the Coulomb potential, considering its partial cancelation with the correlation effects. Functionals in this form are called hybrid functionals.

For including the dynamical and static correlation effects, a formally exact adiabatic continuation formula (Langreth and Perdew, 1975) provides a useful basis

$$E_c = -\frac{e^2}{2} \int_0^1 d\lambda \int \frac{d\omega}{2\pi} \iint d\mathbf{r} d\mathbf{r}' \frac{\chi_\lambda(\mathbf{r}', \mathbf{r}, i\omega) - \chi_0(\mathbf{r}', \mathbf{r}, i\omega)}{|\mathbf{r} - \mathbf{r}'|} \quad (22)$$

Here, χ_λ denotes the density-density response function of the ground state with the electron-electron Coulomb interaction scaled by a factor λ . χ_0 is the Kohn-Sham response function (see also Eq. (32) below). The λ integral is taken with the density ρ fixed. Applying approximations to $\chi_\lambda(\mathbf{r}', \mathbf{r}, i\omega)$, we can obtain approximate E_c formulas. For example, the random phase approximation is widely used to approximate χ_λ , and the corresponding E_c successfully describes the van der Waals effect, a representative correlation effect involving unoccupied orbitals.

For a more thorough review on the LDA, GGA, and orbital-dependent functionals, see, e.g., Engel and Dreizler (2010) and Kümmel and Kronik (2008).

Notes on constructing approximate exchange-correlation functionals

As explained above, analytically derived or exactly calculated asymptotic behavior of $E_{xc}[\rho]$ in the ρ space is utilized to specify the form of the approximate functionals. Still, there remains an ambiguity for general non-uniform ρ , where the exact references are unavailable. Full implementation of the approximate forms finally requires heuristic modeling with tunable parameters.

One approach is to make the model for $E_{xc}[\rho]$ as simple as possible. For example, in constructing the GGA-PBE (Perdew-Burke-Ernzerhof) functional (Perdew et al., 1996), a simple smooth form has been conceived, where the parameters have been unambiguously determined so that it converges to the asymptotic formulas in the limits. A more empirical approach is to refer to data of specific systems for determining the model parameters. Experimentally observed physical quantities or those calculated with accurate wave function methods are often used for this. For example, the prefactor for E^{EXX} is tuned so that accurately calculated cohesive energies of several molecules are optimally reproduced. See, e.g., Mardirossian and Head-Gordon (2017) for a thorough review on a variety of functionals.

An attempt has been recently made to remove the ambiguity stemming from the human construction of the model form. Namely, one adopts an extremely flexible model with a huge number of parameters. The model is by design capable of representing *any* functionals in the infinite parameter limit, so that it can mimic the ideal energy functional $E[\rho]$ as a mapping from ρ to a scalar E . Parameters are tuned with a large amount of reference data. Modern machine learning models and parameter tuning methods are used to implement this scheme (see, e.g., [Schmidt et al., 2019](#) for a review).

Electronic structure

DFT unambiguously defines the quantities related to the charge and spin densities and total energy; magnetic moment, lattice constants, bulk modulus, etc. Relating DFT to electronic single-particle properties is a more complicated issue. This is mainly due to the fact that the occupation number and Kohn-Sham orbital are auxiliary concepts (see Section “[Hohenberg-Kohn theorem and Kohn-Sham equation](#)”) and not directly related to real single particle excitations. Nevertheless, the DFT calculations are widely in practical use for quantitative comparison with experimentally observed excitation spectra. The DFT results (Kohn-Sham wave functions, Kohn-Sham energies, etc.) can also be utilized as a basis for other methods such as the Green’s function theory. In this section, we review those aspects.

Single-particle spectrum

Single-particle excitation can be observed with spectroscopy experiments. Among the single-particle quantities, the fundamental gap, which is the minimum energy required for manipulating one electron within the system at zero temperature, is a key quantity that distinguishes insulators from metals in solids. Here we discuss the discrepancy between the apparent gap in the Kohn-Sham spectra and experimentally observed optical gap (fundamental gap), to recall attention to the interpretation of the band structures obtained within the Kohn-Sham scheme.

Within DFT, the level difference between ground states with different numbers of electrons is well defined. Then, the fundamental gap for an N electron system is given by

$$E_{\text{gap}}(N) = (E(N-1) - E(N)) - (E(N) - E(N+1)) = I(N) - A(N). \quad (23)$$

Here, I and A are the ionization energy and the electron affinity, respectively. In this section, we indicate the dependence on the total number of electrons explicitly for clarity, e.g., $E(N)$ is the total energy of the N electron system. The expression of Eq. (23) is, however, inefficient because we cannot always perform calculations with $N \pm 1$ electrons: For example, in bulk systems, the total N is taken to infinity.

To accommodate DFT to such cases, the extension to systems with fractional electron number $N + \delta$ ($0 < \delta < 1$) has been beneficial. There, the chemical potential μ is introduced, and the occupation number $\{n_i\}$ is extended to allow fractional values. The state can be a mixed state with fractional weights, formed by the pure states of integer electron numbers. The infinitesimal variation of electron numbers can be defined with this formalism. From this Janak’s theorem ([Janak, 1978](#)) is derived, which relates the change in total energy and the occupation numbers as

$$\delta E = \sum_i \delta n_i \varepsilon_i. \quad (24)$$

This theorem is sometimes referred to as it gives the Kohn-Sham orbitals physical meaning. However, one has to recall that n_i and ε_i are artificial variables. Thus, the operation “changing the number of electrons in state i ” is not directly related to adding/subtracting actual electrons. Yet the frontier orbital has physical significance. Within the extended DFT, in the $N + \delta$ electron ground state, only one orbital ϕ_f , which is called the frontier orbital, can have a fractional occupation number ($n_i = 1 \ \forall \ \varepsilon_i < \varepsilon_f$, $n_i = 0 \ \forall \ \varepsilon_i > \varepsilon_f$). Integrating Eq. (24) for $i = f$ from the N to $N \pm 1$ electron states, we obtain:

$$I = \int_N^{N-1} dN \varepsilon_f(N), \quad (25)$$

$$-A = \int_N^{N+1} dN \varepsilon_f(N). \quad (26)$$

Another important consequence of the extended DFT is that the exact N dependence of the total energy is linear between integer N ’s. The fact $I = E(N-1) - E(N) \neq E(N) - E(N+1) = A$ then requires that the derivative of the total energy is discontinuous at the integer points. Therefore, the curve of $E(N)$ appears as a polygonal line with nodes at the integer points ([Perdew et al., 1982](#)). With this fact, the derivative gap

$$E_{\text{gap}}^{\text{deriv}} = \frac{\partial E(N)}{\partial N} \Big|_{N+\delta} - \frac{\partial E(N)}{\partial N} \Big|_{N-\delta} \quad (27)$$

is equated to the fundamental gap. Furthermore, $E_{\text{gap}}^{\text{deriv}}$ satisfies the following equation

$$E_{\text{gap}}^{\text{deriv}} = E_{\text{gap}}^{\text{KS}} + \Delta_{\text{xc}}, \quad (28)$$

where $E_{\text{gap}}^{\text{KS}}$ is the gap between the lowest unoccupied and highest occupied Kohn-Sham states (Kohn-Sham gap) and Δ_{xc} is a spatially constant term so called derivative discontinuity $\frac{\partial E_{\text{xc}}(N)}{\partial N} \Big|_{N+\delta} - \frac{\partial E_{\text{xc}}(N)}{\partial N} \Big|_{N-\delta}$ (Perdew and Levy, 1983). This equality enables us to relate the observed gap to the quantities defined in the N -electron system.

When we use approximate exchange-correlation functionals, $E_{\text{gap}}^{\text{deriv}}$ in Eq. (28) calculated with DFT deviates from the true fundamental gap E_{gap} . Then, the fundamental gap is expressed as

$$E_{\text{gap}} = E_{\text{gap}}^{\text{KS}} + \Delta_{\text{xc}} + \Delta^{\text{straight}}. \quad (29)$$

The final term Δ^{straight} represents a correction term, corresponding to the deviation of the behavior of the approximate $E(N)$ from the ideal segmented straight lines.

The formula Eq. (29) implies some interesting facts of the Kohn-Sham gap $E_{\text{gap}}^{\text{KS}}$. First, even with the exact functional, it does not correspond to the fundamental gap because of the nonzero Δ_{xc} . Second, using the standard functionals such as those within the LDA and GGA, it departs from the fundamental gap by incorrect zero Δ_{xc} and nonzero Δ^{straight} . Recently, functionals design that also takes into account Eq. (29) has been broadly conducted. For example, minimization of Δ^{straight} has been referred to as a criterion for tuning some modern functionals, which improves accuracy for electronic properties. The generalized Kohn-Sham scheme, which includes the orbital-dependent functionals like EXX, helps us to incorporate a major fraction of Δ_{xc} into $E_{\text{gap}}^{\text{KS}}$, so that the Kohn-Sham gap better agrees with the experimental fundamental gap.

See, e.g., Parr and Yang (1995), Mori-Sánchez et al. (2008), and Burke and Kozłowski (2021) for further reading of the topic in this section.

Response function

The general fluctuation-dissipation relationship says that the electronic response to external perturbations is equated to a property in the ground state. In fact, the response function is formulated exactly within the framework of DFT (Hybertsen and Louie, 1987). Suppose the system is perturbed by a change of the external potential $\delta v(\mathbf{r})$ and the charge density distribution changes by $\delta \rho(\mathbf{r})$. The density-density response function $\chi(\mathbf{r}, \mathbf{r}')$ is defined as the linear coefficient relating them:

$$\delta \rho(\mathbf{r}) = \int d\mathbf{r}' \chi(\mathbf{r}, \mathbf{r}') \delta v(\mathbf{r}') \quad (30)$$

The response function χ is given by

$$\chi = \left[1 - \chi_0 \left(\frac{e^2}{|\mathbf{r} - \mathbf{r}'|} + K_{\text{xc}} \right) \right]^{-1} \chi_0 \quad (31)$$

with $K_{\text{xc}}(\mathbf{r}, \mathbf{r}') \equiv \delta^2 E_{\text{xc}} / [\delta \rho(\mathbf{r}) \delta \rho(\mathbf{r}')]$. Here, the quantities are matrices with indices $\mathbf{r}$ and $\mathbf{r}'$. The Kohn-Sham response function χ_0 is defined by

$$\delta \rho(\mathbf{r}) = \int d\mathbf{r}' \chi_0(\mathbf{r}, \mathbf{r}') \delta v_{\text{eff}}(\mathbf{r}'). \quad (32)$$

Applying the perturbation theory to the Kohn-Sham equation, we can write χ_0 in terms of the Kohn-Sham eigenpairs (ϵ_i, ϕ_i) . Note that those expressions are rigorous and well-defined within DFT, though all the ambiguities are condensed in E_{xc} . Using the time-dependent DFT (Section “Extensions”), the time-dependent response function can also be formulated.

Kohn-Sham states in practice

DFT is in principle independent from the Green’s function theory since the former does not define the electron one-particle creation/annihilation operator. Nevertheless, practices are found in the literature where the Kohn-Sham eigenstates are utilized as a basis for calculating quantities formulated in the Green’s function theory, showing remarkable successes in comparing with experiments. Calculations of this kind may be justified by the fact that the Green’s function theory can be made basis-free when the perturbation effects are incorporated up to the infinite order (Hedin, 1965). The Kohn-Sham states, which are introduced as auxiliary quantities (see Section “Hohenberg-Kohn theorem and Kohn-Sham equation”), are then presumed as a good zeroth-order basis, which enables us relatively fast convergence with respect to the order of perturbation.

The combination of DFT and the Green’s function theory has yielded tremendous success in describing the single-particle excitation of materials. The spectral function defined in the Green’s function theory is directly measured by, e.g., angle-resolved photoemission spectroscopy (ARPES). Although the agreement between the Kohn-Sham and experimental spectra is not

Fig. 2 Intensity map of the photoemission spectrum of exfoliated monolayer MoS₂ measured with micrometer-scale ARPES. The GGA-PBE Kohn-Sham band structure including spin-orbit interaction (Zhu et al., 2011) is indicated by the red curves. Reproduced with permission from Jin W, Yeh PC, Zaki N, Zhang D, Sadowski JT, Al-Mahboob A, van der Zande AM, Chenet DA, Dadap JI, Herman IP, Sutter P, Hone J, and Osgood RM (2013) Direct measurement of the thickness-dependent electronic band structure of MoS₂ using angle-resolved photoemission spectroscopy. *Physical Review Letters* 111: 106801, Copyright (2013) by the American Physical Society.

exchange term to the functional or calculating the self-energy by perturbation theory with the Kohn-Sham eigenbasis. The GW approximation (see, e.g., [Aryasetiawan and Gunnarsson, 1998](#) for a review) serves as a standard method for calculating the self-energy. It treats the long-range exchange-correlation effects efficiently under weak to strong Coulomb interaction.

When the correlation effects become even stronger, the one-electron description may break down. Such a situation occurs in so-called strongly-correlated materials, where energy scales of the Coulomb interaction and kinetic energies compete. Typical strongly-correlated materials are, for example, transition-metal oxides with partially-filled *d*-electron shells and heavy-fermion materials with partially-filled *f*-electron shells. The bandwidth *W* of partially-filled orbitals in these materials is typically narrow, and becomes comparable or even smaller than the onsite Coulomb interaction *U*. For such systems, the band theory based on the KS states becomes inaccurate, and it often fails to describe the spectral property around the Fermi level. For example, when we regard the Kohn-Sham energy eigenvalues as the poles of the spectral function, DFT cannot reproduce the charge gap opening in Mott insulators, where electrons are localized due to the strong Coulomb repulsion. To incorporate such many-body effects, a combination of DFT and many-body methods, such as the dynamical mean-field theory and the variational Monte Carlo method, has been developed. For more details of the conceptual and practical aspects of the combination, see, e.g., [Kotliar et al. \(2006\)](#) and [Imada and Miyake \(2010\)](#).

Nuclear dynamics

DFT is also useful in investigating nuclear dynamics. This is because the total energy of the electronic system plays a role as the potential for the atomic vibration (Eq. 3). Here, we discuss the expressions for the forces acting on nuclei and the interatomic force constants, which are used in structure optimization and phonon dispersion calculations, respectively.

Forces acting on nuclei

The force acting on *I*th nucleus F_I is given by the derivative of the energy surface

$$F_I = -\frac{\partial E(\{\mathbf{R}\})}{\partial \mathbf{R}_I}. \quad (33)$$

The forces on nuclei vanish ($F_I = 0$) at equilibrium geometry. Therefore, one can perform structure optimization by minimizing the forces on the nuclei. In practice, the forces (first derivative of the energy surface) can be estimated efficiently using the Hellmann-Feynman theorem ([Hellmann, 1937](#); [Feynman, 1939](#)).

Interatomic force constants

Here, we show how the normal vibrational modes are derived. We consider the displacement of *I*th nucleus $\mathbf{u}_I$ from the equilibrium position $\mathbf{R}_I^{(0)}$. The position of the *I*th nucleus reads

$$\mathbf{R}_I = \mathbf{R}_I^{(0)} + \mathbf{u}_I, \quad (34)$$

Then, the kinetic energy *T* for the atomic vibration is given by

$$T = \frac{1}{2} \sum_I M_I |\dot{\mathbf{u}}_I|^2 = \frac{1}{2} \sum_{I\alpha} M_I (\dot{u}_I^\alpha)^2. \quad (35)$$

Here, α is the cartesian component of the displacement ($\alpha = x, y, z$). For the potential energy *U*, we apply the harmonic approximation:

$$U = E(\{\mathbf{R}^{(0)} + \mathbf{u}\}) - E(\{\mathbf{R}^{(0)}\}) \quad (36)$$

$$\simeq \frac{1}{2} \sum_{I\alpha} \sum_{I'\alpha'} \frac{\partial^2 E(\{\mathbf{R}\})}{\partial R_I^\alpha \partial R_{I'}^{\alpha'}} u_I^\alpha u_{I'}^{\alpha'}. \quad (37)$$

Note that the first-order terms with respect to the displacement vanish at the equilibrium geometry.

From the expression of *U* and *T*, one can derive the secular equation, which determines the frequency and displacement pattern of the normal vibrational modes:

$$\sum_{I'\alpha'} \left(C_{I,I'}^{\alpha,\alpha'} - M_I \omega^2 \delta_{II'} \delta_{\alpha\alpha'} \right) u_{I'}^{\alpha'} = 0, \quad (38)$$

where *C* is the matrix of so called interatomic force constants

$$C_{l,l'}^{\alpha\alpha'} = \frac{\partial^2 E(\{\mathbf{R}\})}{\partial R_l^\alpha \partial R_{l'}^{\alpha'}}. \quad (39)$$

The interatomic force constants play a role as “spring constants” of the “springs” between nuclei. In crystals, Eq. (38) becomes block diagonal in momentum space, and the normal modes are labeled by wave vectors. Then, the frequencies of the normal modes give the phonon dispersion in solids.

In practical calculations, there exist mainly two approaches to estimate the interatomic force constants. One is a direct method, called frozen phonon, in which forces are computed under finite amplitudes of displacements and the interatomic force constants are estimated from finite differences of the forces. The other method relies on the density-functional perturbation theory (DFPT) (Baroni et al., 2001), which shows that the interatomic force constants can be computed from the ground-state electron density and its linear response to the atomic displacements. Therefore, the frozen phonon method performs supercell calculations with finite atomic displacements, whereas the DFPT performs linear response calculations to the displacements.

As an example of phonon calculations, we show, in Fig. 3, the phonon dispersions of elemental semiconductors, Si and Ge, calculated using the DFPT (Giannozzi et al., 1991). The DFPT results show a good agreement with experiments.

Recent topics

Here, among many recent topics, we introduce two advances related to phonon properties: anharmonicity and structure prediction.

Anharmonicity is a deviation of the atomic vibrations from a harmonic oscillator, which arises from higher-order terms of the expansion of energy difference with respect to atomic displacements (Eq. 36). The anharmonic terms are crucial in describing thermal properties of atomic vibrations, such as thermal expansion, thermal conductivity, and thermodynamic stability. Optimizing these properties leads to functional materials. For example, controlling the phonon lifetime and achieving low thermal conductivity in the phonon-contributing part is essential in designing good thermoelectric materials. For more details of the recent advancements in the computation of anharmonicity, see, e.g., Tadano and Tsuneyuki (2018); McGaughey et al. (2019).

One of the dreams of materials scientists would be a theoretical prediction of functional materials. Structure prediction of materials is a very challenging task because the energy landscape $E(\{\mathbf{R}\})$ is a complicated object with a huge number of local minima. Recently, there has been a tremendous advance in numerical tools to explore the complex potential energy surface (see, e.g., Andreoni and Yip, 2020). A remarkable success of the crystal-structure search algorithm so far is, for example, a prediction of high-temperature superconductors under extremely high pressure (see, e.g., Flores-Livas et al. (2020) for details).

Practical guide

Program packages

Nowadays, there are a variety of DFT open source packages. Some of them are introduced in Talirz et al. (2021). See also, e.g., https://en.wikipedia.org/wiki/List_of_quantum_chemistry_and_solid-state_physics_software for a list.

Reproducibility

In the practical calculations of DFT, most of the open-source programs employ the Kohn-Sham formalism (see Section “Hohenberg-Kohn theorem and Kohn-Sham equation”). When the same exchange-correlation functional is employed, different programs solve the same Kohn-Sham equations. Ideally, all codes should give the same solution. However, depending on, for example, the type of the basis set [plane-wave, (linearized) augmented plane wave (L)APW, linear muffintin orbital (LMTO), and so on] and approximate ionic potentials [norm-conserving and ultrasoft pseudopotentials, projector augmented wave (PAW) method, and so on], the accuracy may differ among available packages. Therefore, it is an important task for the community to check the reproducibility of the DFT calculations. Recently, such a systematic benchmark has started to be performed. For example, Lejaeghere et al. (2016) compared various DFT packages for solids and confirmed that widely-used codes and methods give essentially identical solutions.

Conclusion

DFT is currently one of the most standard and established methods for electronic structure calculations. Many DFT open sources have been developed in recent years, allowing a wide range of researchers to enjoy DFT calculations. Nowadays, DFT is widely used to calculate the properties of solids. In addition to the ground-state electronic structure calculations, DFT is also useful for calculating excitation spectra (both single- and two-particle) and nuclear dynamics. Care must be taken then in interpreting the eigenvalues of the Kohn-Sham equation.

Although it is impossible to cover all of the vast DFT-related topics, we have provided an introductory explanation of some of them in this chapter. Please refer to the references for more details of advanced topics. We hope this chapter will be of some help to understand what can be done with DFT.

Abstract

The sign problem in quantum Monte Carlo (QMC) simulations appears to be an extremely hard yet interesting problem. In this article, we present a pedagogical overview of the origin of the sign problem in various quantum Monte Carlo simulation techniques, ranging from the world-line and stochastic series expansion Monte Carlo for boson and spin systems to the determinant and momentum-space quantum Monte Carlo for interacting fermions. We point out the basis dependency of the sign problem and summarize the progresses to cure, ease and even make use of the sign problem over the years, such as symmetry analysis of the underlying Hamiltonian, basis optimization in writing down the partition functions and many others. Moreover, we state that although traditional lore says that in the case of sign problem, the average sign in QMC simulation approaches zero exponentially fast with the space-time volume of the configurational space, there are recent breakthroughs showing this is not always the case. Based on the properties of the partition function for finite size systems, one could distinguish when the average sign has the usual exponential scaling and when it is bestowed with an algebraic scaling at the low-temperature limit. Fermionic QMC simulations with such algebraic sign problems have been successfully carried out for extended Hubbard-type and quantum Moiré lattice models.

Introduction

The quantum Monte Carlo (QMC) method is an extremely powerful and unbiased method for studying strongly correlated systems, especially in condensed matter, high energy and quantum material research (Foulkes et al., 2001; Carlson et al., 2015; Assaad and Evertz, 2008; Sandvik, 2010; Xu et al., 2019a), where the quantum many-body lattice models are in general analytically intractable. In QMC simulation, the partition function of the interacting problem is cast into a sum (or integral) over configurations in a chosen basis, and the important sampling scheme could in principle cover the exponentially large configurational space in polynomial time.

However, such practice is often hindered by the infamous “Sign Problem” (Loh et al., 1990). Sign problem means the weights of configurations in the QMC simulation become negative or even complex, and therefore the configurational weights in the Monte Carlo process cannot be further interpreted as classical probabilities, and the minus or even complex sign will render the QMC simulation with exponential complexity for obtaining the data with the same quality compared with the simulations without sign problem. It has been proven that if we could find a method to solve a nondeterministic polynomial (NP) hard problem efficiently, the method can be used to solve the QMC simulations with the sign problem (Troyer and Wiese, 2005). It’s important to note that this doesn’t mean the sign problem is considered to be NP-hard (Kaul et al., 2013), nor is it inconsistent with performing polynomial-time QMC simulation of specific cases that have a negative or complex sign.

The origin of the sign problem has no universal explanation, but it is believed to come from the quantum mechanic properties of the constituent particles in the many-body systems, i.e., fermions, bosons or spins. Frustrated spin systems often have a sign problem because the off-diagonal operators in the Hamiltonian usually bring a negative amplitude (Takasu et al., 1986; Hatano and Suzuki, 1992) and the number of off-diagonal operators can be odd for a particular configuration. While in fermionic systems, negative weights usually arise from the Pauli exclusion principle (Troyer and Wiese, 2005) or different Hubbard-Stratonovich decoupling (Hirsch, 1985) schemes (which means decoupling the quartic fermion interaction term into a certain quadratic basis). At the same time, there are also proposals that the negative sign of a configuration is a topological invariant, which is an imaginary time counterpart of the Aharonov-Anandan phase and can be reduced to a Berry phase in the adiabatic limit (Iazzi et al., 2016). And the sign problem has even been linked to quantum phase transitions (Mondaini et al., 2022; Tarat et al., 2022). Moreover, it was shown recently that some interacting models may have an intrinsic sign problem, which cannot be cured (Hastings, 2016; Ringel and Kovrizhin, 2017; Smith et al., 2020; Golan et al., 2020). In general, a unified description of the sign problem is still missing. These different situations where the sign problem occurs in QMC simulations will be discussed in a case based manner in sections “Configurational weight in classical Monte Carlo simulation” and “Configurational weight in quantum Monte Carlo simulation” of this article.

Fortunately, there are many cases of quantum lattice models where there are no or weak (polynomial instead of exponential scaling) sign problems and Monte Carlo calculations can be carried out with polynomial complexity. In frustrated magnet lattice models, there is no sign problem for some bilayer models (Alet et al., 2016; Ng and Yang, 2017; Honecker et al., 2016; Stapmanns et al., 2018; StefanWessel et al., 2017) within certain parameters. Inspired by the absence of sign problems in the above models, one can choose those models as sign-problem-free reference systems and extend the simulation basis from spin to singlet-triplet or even plaquette bases, and it has been shown that QMC simulations can be carried out to the parameter space for few important 2D frustrated lattice models (such as the Shastry-Sutherland antiferromagnetic spin model) where there were sign problems in the original spin basis (Wessel et al., 2018; D’Emidio et al., 2020). Interacting fermion models (mainly Hubbard-type) at a certain basis with certain symmetries, such as anti-unitary symmetry, have been proven to be sign problem free (Congjun and Zhang, 2005; Lang et al., 1993; Koonin et al., 1997; Hands et al., 2000). Flat band quantum Moré lattice models with $C_2T + C_2P$ symmetries can also ensure that there are no sign problems (Xu et al., 2021a; Johannes et al., 2021; Ouyang and Xu, 2021; Zhang et al., 2021). There also exist cases where one can use Majorana representation to avoid the sign problem, split the fermionic operator into Majorana fermions and reuse the anti-unitary symmetry (Li et al., 2015, 2016; Li and Yao, 2019; Wei et al., 2016; Wang et al., 2015). In addition, basis transformation (D’Emidio et al., 2020; Shinaoka et al., 2015; Levy and Clark, 2021; Torlai et al., 2020; Hangleiter et al., 2020; Klassen et al., 2020; Marvian et al., 2019; Kim et al., 2020; Rossi, 2017; Rossi et al., 2017), Lefschetz thimbles (Ulybyshev et al., 2020; Alexandru et al., 2020), meron cluster (Chandrasekharan and Wiese, 1999), Fermi bags (Huffman and Chandrasekharan, 2014), split-orthogonal group (Wang et al., 2015), Majorana positivity (Wei et al., 2016), semigroup approach (Wei, 2017) and pseudo-unitary group (Xu et al., 2019b), automatic differentiation (Wan et al., 2020), machine learning techniques (Broecker et al., 2017; Wynen et al., 2021) and adiabatic method (Vaezi et al., 2021), or through some systematic expansion (Lawrence, 2020) can also solve or ease some sign problems. These cases will be discussed in sections “What is the sign problem?” and “How to cure, ease and make use of the sign problem” of this article.

If there is sign problem in the QMC simulation, the usual simulation approach is to reweight: one can take the magnitude of the original weight (or magnitude of the real part) as the new weight, and add the sign into the sampling process of physical observables and divide the average sign $\langle s \rangle$. This approach does not solve the sign problem, but only casts it into a different form. The average sign over the Monte Carlo sampling will appear in the denominator, so the average sign will affect how long it will take to obtain meaningful expectation values with controlled errorbars in the simulation. Usually $\langle s \rangle \propto e^{-N\beta\Delta f}$, where Δf is the free energy difference of the two systems before and after reweighting. This means sign often decays exponentially. And there is a lot of research that support the viewpoint. No matter what lattice (hypercubic, ladder, depleted square, Lieb, honeycomb, kagome, and triangular lattices) or parameter (temperature, interaction strength, and density), the sign usually decays exponentially. There is a good summary (Igloukov et al., 2015) of the sign data for different geometry and parameters.

But recent developments have changed this viewpoint, there are cases in the Hubbard model at certain fillings where the average sign does not decay exponentially (Tarat et al., 2022; Ibarra-García-Padilla et al., 2021) and we have found that it is possible to prove that the average sign of quantum many-body lattice models acquire algebraic sign structure (Ouyang and Xu, 2021; Zhang et al., 2021), if their finite size partition functions satisfy the *Sign bound theory*. The details on the theory and its application on the systems with extended or long-range interaction such as the extended Hubbard (Ouyang and Xu, 2021; Da Liao et al., 2022) and quantum Moiré lattice models (Xu et al., 2018, 2021a,b; Zhang et al., 2021; Liao et al., 2021; Da Liao et al., 2021; Pan et al., 2022), are given in section “Sign bound theory” of this article.

Configurational weight in classical Monte Carlo simulation

Before presenting the details of the sign problem, we first discuss classical Monte Carlo simulation briefly such that the origin of the sign problem manifests naturally. In classical Monte Carlo, the partition function at temperature T is written as follows

$$Z = \text{Tr}[e^{-\beta H}] = \sum_{C \in \Omega} e^{-\beta E(C)} = \sum_{C \in \Omega} W(C), \quad (1)$$

where $\beta = \frac{1}{k_B T}$, k_B is the Boltzmann constant, and C stands for the configurations in the configurational space Ω , which is exponentially large in system size, such as 2^{L^d} and 4^{L^d} for d dimensional spin or fermion systems with linear dimension L . Once

the partition function is written as a sum of Boltzmann weights $e^{-\beta E(C)}$, it's clear that in the classical Monte Carlo the $W(C)$ corresponding to different configurations are always positive and real numbers. So one can easily carry Monte Carlo updates in a Markov chain by calculating the ratio of weights of different configurations.

For example, as shown in Fig. 1, the Hamiltonian of the classical 2d Ising model is: $H = \sum_{i,j} J_{i,j} s_i s_j$, where s_i denotes the state of the i -th spin which takes the value of ± 1 (up or down), $J_{i,j}$ is the interaction strength. For the configuration in Fig. 1, the corresponding weight is $e^{-\beta \sum_{i,j} E_{i,j}(C)}$.

We know the expectation value of observable O is

$$\langle O \rangle = \frac{1}{Z} \text{Tr}[O e^{-\beta H}] = \frac{1}{Z} \sum_{C \in \Omega} O(C) W(C). \quad (2)$$

For the classical case, since $W(C)$ is a real number and $W(C) \geq 0$, one can carry out the Monte Carlo steps and obtain N_b configurations $\{C_i\}$ from Ω , according to the distribution $p(C_i) = W(C_i)/Z$. Here N_b is number of sampling bins, and then the average value of the samples is the expectation value of the physical quantity O

$$\langle O \rangle \approx \bar{O} = \frac{1}{N_b} \sum_{i=1}^{N_b} O(C_i). \quad (3)$$

The statistical error corresponding to such an estimate of the mean value is (Geyer, 2011)

$$\Delta O = \sqrt{\frac{\text{Var}(O) 2\tau_O^{\text{int}}}{N_b}}, \quad (4)$$

where $\text{Var}(O)$ is the variance of O and the integrated autocorrelation time τ_O^{int} is a measure of the autocorrelations of the sequence $\{O(C_i)\}$

$$\tau_O^{\text{int}} = \frac{1}{2} + \sum_{t=1}^{\infty} A_O(t), \quad (5)$$

and the autocorrelation function $A_O(t)$ for a quantity O is defined as

$$A_O(t) = \frac{\langle O(C_{i+t}) O(C_i) \rangle - \langle O \rangle^2}{\langle O \rangle^2 - \langle O \rangle^2}. \quad (6)$$

In principle, since in classical Monte Carlo weights are always real and positive and the statistical errors are inversely proportional to the number of bins $\Delta O \propto \frac{1}{\sqrt{N_b}}$, one can carry out Monte Carlo sampling in polynomial time to achieve controlled expectation values (critical slowing down is not taken into account).

Configurational weight in quantum Monte Carlo simulation

However, when we consider quantum Monte Carlo (QMC) simulation, the weight may become a negative or even a complex number and cause the sign problem in the sampling. In QMC, quantum many-body problems in d dimension are usually mapped onto a classical system in $d + z$ dimension, where z is the dynamic exponent of the problem and usually taken to be 1 in practically simulations (Suzuki, 1976). Depending on the quantum lattice models, there are many different QMC algorithms, such as world-line Monte Carlo (Suzuki, 1976; Evertz et al., 1993; Prokof'ev et al., 1998; Hirsch et al., 1982), stochastic series expansion (SSE) (Sandvik and Kurkijärvi, 1991; Sandvik, 1992), determinant quantum Monte Carlo (DQMC) (Hirsch, 1985; White et al., 1989), momentum space quantum Monte Carlo (Xu et al., 2021a; Pan et al., 2022; Dai, 2022) and so on. The form of the weights in these methods and the origin of the sign problem are not the same and we will discuss them one by one.

Fig. 1 Classical Ising configuration of the example $E(C) = \sum_{i,j} E_{i,j}$ and $E_{i,j} = J_{i,j}$ and $E_{i,k} = -J_{i,k}$.

$$\begin{aligned} Z &= \text{Tr} \left[e^{-\beta \hat{H}} \right] = \text{Tr} \left[e^{-M \Delta \tau \hat{H}} \right] = \text{Tr} \left[\left(e^{-\Delta \tau \hat{H}_1} e^{-\Delta \tau \hat{H}_2} \right)^M \right] + \mathcal{O}(\Delta \tau^2) \\ &= \sum_{i_1, \dots, i_{2M}} \langle i_1 | e^{-\Delta \tau \hat{H}_1} | i_{2M} \rangle \langle i_{2M} | e^{-\Delta \tau \hat{H}_2} | i_{2M-1} \rangle \dots \\ &\quad \langle i_3 | e^{-\Delta \tau \hat{H}_1} | i_2 \rangle \langle i_2 | e^{-\Delta \tau \hat{H}_2} | i_1 \rangle, \end{aligned} \quad (7)$$

For example, for spin-1/2 XXZ model in a chain, with Hamiltonian

$$\hat{H} = J_x \sum_i \left(\hat{S}_i^x \hat{S}_{i+1}^x + \hat{S}_i^y \hat{S}_{i+1}^y \right) J_z \sum_i \hat{S}_i^z \hat{S}_{i+1}^z. \quad (8)$$

$$\hat{H} = \underbrace{\sum_n \hat{H}^{(2n+1)}}_{\hat{H}_+} + \underbrace{\sum_n \hat{H}^{(2n+2)}}_{\hat{H}_-}, \quad (9)$$

For continuous-time world-lines, the expansion may vary, but the form of the weights is broadly similar. If $\hat{H} = \hat{H}_0 + \hat{V}$, and $\hat{V}$ is a perturbation (Prokof'ev et al., 1998). We define $e^{-\tau\mathcal{H}_0}\hat{U}(\tau) = e^{-\tau(\mathcal{H}_0+\hat{V})}$ and $\hat{V}(\tau) = e^{\tau\mathcal{H}_0}\hat{V}e^{-\tau\mathcal{H}_0}$. Then

Fig. 2 World line configuration for the XXZ model. (a) The bold lines correspond to the imaginary time evolution of spin up states, and the unpassed points correspond to states with spin down. (b) Corresponding weights of matrix elements in different cases. We see that the negative weight case corresponds to the spin flip operation.

$$\begin{aligned}
Z &= \text{Tr} \left[e^{-\beta \hat{\mathcal{H}}_0} \hat{U}(\beta) \right] \\
&= \text{Tr} \left[e^{-\beta \hat{\mathcal{H}}_0} \left(1 - \int_0^\beta d\tau_1 \hat{V}(\tau_1) + \int_0^\beta d\tau_2 \int_0^{\tau_2} d\tau_1 \hat{V}(\tau_2) \hat{V}(\tau_1) - \dots \right) \right] \\
&= \text{Tr} \left[\sum_{n=0}^{\infty} \frac{(-1)^n}{n!} \int_0^\beta d\tau_n \int_0^{\tau_n} d\tau_{n-1} \dots \int_0^{\tau_2} d\tau_1 e^{-(\beta - \tau_n) \hat{\mathcal{H}}_0} \hat{V} e^{-(\tau_n - \tau_{n-1}) \hat{\mathcal{H}}_0} \times \hat{V} \dots \hat{V} e^{-\tau_1 \hat{\mathcal{H}}_0} \right] \\
&= \sum_{n=0}^{\infty} \frac{(-1)^n}{n!} \sum_{\phi_n, \dots, \phi_1} \int_0^\beta d\tau_n \int_0^{\tau_n} d\tau_{n-1} \dots \int_0^{\tau_2} d\tau_1 \langle \phi_1 | e^{-(\beta - \tau_n) \hat{\mathcal{H}}_0} | \phi_1 \rangle \langle \phi_1 | \hat{V} | \phi_n \rangle \\
&\quad \times \langle \phi_n | e^{-(\tau_n - \tau_{n-1}) \hat{\mathcal{H}}_0} | \phi_n \rangle \langle \phi_n | \hat{V} | \phi_{n-1} \rangle \dots \langle \phi_2 | \hat{V} | \phi_1 \rangle \langle \phi_1 | e^{-\tau_1 \hat{\mathcal{H}}_0} | \phi_1 \rangle.
\end{aligned} \tag{10}$$

where $\hat{U}(\tau) = 1 - \int_0^\tau d\tau' \hat{V}(\tau') \hat{U}(\tau')$.

Stochastic series expansion

The stochastic series expansion (SSE) method (Sandvik and Kurkijärvi, 1991; Sandvik, 1992) Taylor expands the partition function, and it can be shown that the expansion of finite size systems can be safely truncated,

$$\begin{aligned}
Z &= \text{Tr} \left[\exp^{-\beta \hat{H}} \right] = \sum_{n=0}^{\infty} \frac{(-\beta)^n}{n!} \text{Tr} \left[\hat{H}^n \right] \\
&= \sum_{n=0}^{\infty} \sum_{i_1, \dots, i_n} \frac{(-\beta)^n}{n!} \langle i_1 | \hat{H} | i_2 \rangle \langle i_2 | \hat{H} | i_3 \rangle \dots \langle i_n | \hat{H} | i_1 \rangle \\
&\equiv \sum_{n=0}^{\infty} \sum_{i_1, \dots, i_n} p(i_1, \dots, i_n) \equiv \sum_{C \in \Omega} W(C),
\end{aligned} \tag{11}$$

which is similar to the case of the world-line, the final sign of the weight is also determined by the number of negative matrix elements multiplied, i.e., usually by the number of off-diagonal elements (on the spin $\hat{S}_i^z$ basis, the spin-flip term $\hat{S}_j^+ \hat{S}_{j+1}^- + \hat{S}_j^- \hat{S}_{j+1}^+$ is off-diagonal). For bipartite lattices such as square or honeycomb with the periodic boundary condition in space-time, it can be shown that the number of the off-diagonal operator is always even such that their product in the configurational weight will be positive, however, for non-bipartite lattices, such as triangle and kagome, the number of the off-diagonal operators can be odd such that the SSE simulation will have a sign problem. We note that there are recent developments in frustrated magnet lattice models, and some bilayer models (Alet et al., 2016; Ng and Yang, 2017; Honecker et al., 2016; Stapmanns et al., 2018; StefanWessel et al., 2017) within certain parameters with cluster basis are sign-problem-free. Inspired by these works and considering the model that has the same ground state as the above model, one can extend the simulation basis from spin to singlet-triplet or even plaquette bases, and it has been shown that SSE-QMC simulations for few important 2D frustrated lattice models, such as the Shastry-Sutherland antiferromagnetic spin model, can be carried out to the parameter space where there was a sign problem in the original spin basis (Wessel et al., 2018; D'Emidio et al., 2020).

Determinant Quantum Monte Carlo

For interacting fermion models, one uses different ways to write down the partition functions. In determinant quantum Monte Carlo (DQMC) (Hirsch, 1985; White et al., 1989), auxiliary fields are introduced to decouple interactions through the Hubbard-Stratonovich transformation. Taking the Hubbard model as an example, Suzuki-Trotter decomposition is still necessary

$$Z = \text{Tr} \left[e^{-\Delta\tau \hat{H}_1} e^{-\Delta\tau \hat{H}_0} e^{-\Delta\tau \hat{H}_1} e^{-\Delta\tau \hat{H}_0} \dots e^{-\Delta\tau \hat{H}_1} e^{-\Delta\tau \hat{H}_0} \right], \tag{12}$$

where $\hat{H}_0 = -t \sum_{\langle i,j \rangle} (\hat{c}_i^\dagger \hat{c}_j + h.c.)$ and $\hat{H}_1 = U \sum_i (\hat{n}_{i\uparrow} - \frac{1}{2})(\hat{n}_{i\downarrow} - \frac{1}{2})$. $\langle i,j \rangle$ means nearest-neighbor hopping. Then Hubbard-Stratonovich transformation gives

$$\begin{aligned}
e^{-\Delta\tau \hat{H}_1} &= \prod_i e^{-\Delta\tau U (\hat{n}_{i\uparrow} - \frac{1}{2})(\hat{n}_{i\downarrow} - \frac{1}{2})} \\
&= \prod_i \gamma \sum_{s_{ij}=\pm 1} e^{\alpha s_{ij} (\hat{n}_{i\uparrow} - \frac{1}{2})(\hat{n}_{i\downarrow} - \frac{1}{2})} \\
&= \gamma^N \sum_{s_{ij}=\pm 1} \left(\prod_i e^{\alpha s_{ij} \hat{n}_{i\uparrow}} \prod_i e^{-\alpha s_{ij} \hat{n}_{i\downarrow}} \right),
\end{aligned} \tag{13}$$

where $\gamma = \frac{1}{2} e^{-\Delta\tau U/4}$, $\cosh(\alpha) = e^{\Delta\tau U/2}$. Since we have $\text{Tr} \left[e^{-\sum_{ij} \hat{c}_i^\dagger A_{ij} \hat{c}_j} e^{-\sum_{ij} \hat{c}_i^\dagger B_{ij} \hat{c}_j} \right] = \text{Det}(1 + e^{-A} e^{-B})$, then the partition function is

$$\begin{aligned}
Z &= \sum_{s_{i,l}=\pm 1} \gamma^{NL_\tau} \text{Tr}_F \left\{ \prod_{l=1}^{L_\tau} \left[\left(\prod_i e^{s_{i,l} \hat{n}_i} \right) (e^{-\Delta\tau c_l^\dagger T c_l}) \left(\prod_i e^{-s_{i,l} \hat{n}_i} \right) (e^{-\Delta\tau c_l^\dagger T c_l}) \right] \right\} \\
&= \gamma^{NL_\tau} \sum_{\{s_{i,l}\} \sigma=\uparrow\downarrow} \prod \text{Det}[\mathbf{I} + \mathbf{B}^\sigma(L_\tau \Delta\tau, (L_\tau - 1)\Delta\tau) \cdots \mathbf{B}^\sigma(\Delta\tau, 0)],
\end{aligned} \tag{14}$$

where

$$\begin{aligned}
\mathbf{B}^\uparrow(l_2 \Delta\tau, l_1 \Delta\tau) &= \prod_{l=l_1+1}^{l_2} e^{\alpha \text{Diag}(\vec{s}_l)} e^{-\Delta\tau T} \\
\mathbf{B}^\downarrow(l_2 \Delta\tau, l_1 \Delta\tau) &= \prod_{l=l_1+1}^{l_2} e^{-\alpha \text{Diag}(\vec{s}_l)} e^{-\Delta\tau T}.
\end{aligned} \tag{15}$$

and $\text{Diag}(\vec{s}_l)$ is a diagonal matrix with diagonal elements $s_{i,l}$. For the space-time configuration $\{s_{i,l}\}$, the calculation of weight is converted to the calculation of the determinant of matrices. Without prior knowledge such as symmetry analysis or energy spectrum (Zhang et al., 2021), the determinant of a matrix doesn't have to be a positive real number. It is worth noting that the Hubbard-Stratonovich transformation which introduces auxiliary fields is also one of the causes of the sign problem. For example, using the world-line method, the one-dimensional Hubbard model has no sign problem (Assaad and Evertz, 2008; Hirsch et al., 1982), but for DQMC, usually there is a sign problem (Iglovikov et al., 2015). A Markov chain for the DQMC simulation for the 2d Hubbard model, with $L \times L \times \beta$ and the auxiliary fields for three consecutive configurations is given in Fig. 3.

What is the sign problem?

With the above preparation, we now discuss the real content of the sign problem. As the name implies, the simplest and most straightforward definition of the sign problem is that, the weights (probabilities) in the Monte Carlo simulation $p(C_i) = W(C_i)/Z$ are negative or become a complex number.

For the real time evolution of a quantum mechanic state, this is obviously going to happen, because the time evolution operator is e^{-itH} and the corresponding configurational weight $W(C) \sim \exp(iS(C))$, here $S(C)$ is the action function of configuration C , which is time integral of Lagrangian $L: S = \int dt L(x, \dot{x})$. It's not surprising that now the weight might be a complex number. While if we consider the ensemble average at the thermal equilibrium state for classical statistical problems such as the Ising model in section "Configurational weight in classical Monte Carlo simulation," configurational weight $W(C) \sim \exp(-\beta H(C))$, is real and positive.

When we discuss algorithms that do not suffer from the sign problem (Troyer and Wiese, 2005), it usually means that the algorithm needs polynomial complexity to evaluate the thermal average $\langle O \rangle$, i.e., with the system size $N = L^d$ and inverse temperature $\beta = \frac{1}{k_B T}$, the computational time required to make the relative error $\Delta O / \langle O \rangle$ less than ε is called $t(\varepsilon, N, \beta)$. If $t(\varepsilon, N, \beta)$ grows polynomially with N and β , then there exist integers n and m and a constant $\kappa < \infty$ such that

$$t(\varepsilon, N, \beta) < \kappa \varepsilon^{-2} N^n \beta^m. \tag{16}$$

Such complexity is tractable with realistic Monte Carlo simulation in both human and machine time.

One thing that needs to be clarified is that sign problem doesn't mean one cannot carry out Monte Carlo simulation on finite-size system. If there is sign problem, the usual expedient (Loh et al., 1990) is to introduce a reference system which is sign-problem-free, by reweighting

$$\langle O \rangle = \frac{\sum_C O(C_i) W(C_i)}{\sum_C W(C_i)} = \frac{\sum_C O(C_i) s(C_i) |W(C_i)| / \sum_C |W(C_i)|}{\sum_C s(C_i) |W(C_i)| / \sum_C |W(C_i)|} \equiv \frac{\langle O s \rangle'}{\langle s \rangle'}, \tag{17}$$

Fig. 3 The space-time auxiliary field $\{s_{i,l}\}$ introduced by Hubbard-Stratonovich transformation lives on the lattice of $d + 1$ dimension (here $d = 2$ with linear system size L), and we perform the calculation of Markov chain Monte Carlo by flipping the auxiliary field on the space-time lattice with the corresponding probability. Here the notation $\mathbf{B}(\vec{s}(l))$ corresponds to the matrix containing the auxiliary field of imaginary time layer l , shown in Eq. (15).

where $s(C_i) = \frac{W(C_i)}{|W(C_i)|}$ and $\langle O \rangle' = \frac{\sum_C O(C_i) |W(C_i)|}{\sum_C |W(C_i)|}$. The average of sign, $\langle s \rangle = Z/Z'$, which is just the ratio of the partition function of the system $Z = \sum_C W(C_i)$ with weights $W(C_i)$ and the reference system used for sampling with another partition function $Z' = \sum_C |W(C_i)|$.

As the partition function is usually an exponential form of the free energy, then $\langle s \rangle = Z/Z' = \exp(-\beta N \Delta f)$, where Δf is the free energy densities differences of Z and Z' . When there is a sign problem, the term $\langle s \rangle$ in the denominator needs to be taken into account when calculating the mean value of quantity, so the relative error $\Delta s / \langle s \rangle$ of the sign is very important, and it usually increases exponentially with inverse temperature β and system size N

$$\frac{\Delta s}{\langle s \rangle} = \frac{\sqrt{(\langle s^2 \rangle - \langle s \rangle^2)/N_b}}{\langle s \rangle} = \frac{\sqrt{1 - \langle s \rangle^2}}{\sqrt{N_b} \langle s \rangle} \sim \frac{e^{\beta N \Delta f}}{\sqrt{N_b}} + O(\langle s \rangle), \quad (18)$$

where N_b is the number of bins. In most cases, Δf is a quantity that doesn't change very much in the simulation, so when there is a sign problem, the QMC simulation usually takes exponential time to have a reasonable estimation of the errorbars for physical observables.

The exponential computation time seems to imply that the sign problem may be an nondeterministic polynomial (NP) problem, but is it an NP-hard problem? Here NP problems are the set of decision problems solvable in polynomial time by a nondeterministic Turing machine, and an NP-hard problem means every problem in NP can be reduced in polynomial time to it. At present, the answer still seems unclear, but explicit examples can deepen our understanding.

People try to construct a simulation with sign problem, and the calculation of its physical quantity can be transformed into a solution of an NP-complete problem. Here a problem is NP-complete means it is both NP and NP-hard. It is suggested that if the polynomial-time solution corresponding to the sign problem is found, the polynomial-time solution of the NP-complete problem can also be found, that is, the sign problem is an NP-hard problem. In [Troyer and Wiese \(2005\)](#), people consider a well-known special case of the classical Ising spin glass model. One can map it to a NP-hard graph problem, such as "finding ground energy" to another problem "finding a cocycle of minimum weight while a two-level grid $G = (V, E)$, and a weighting function $J : E \rightarrow \{-1, 0, 1\}$ are given" ([Barahona, 1982](#)). Here a graph $G = (V, E)$ consists of a set of vertices V , and a set E of unordered pairs of different vertices, called edges. Then it is possible to introduce a corresponding NP-complete problem ([Troyer and Wiese, 2005](#)): for given constant C , does the ground state have energy $E_0 \leq C$? And then one can map the classical Ising spin glass model to quantum Ising spin glass model with $\sigma_i^x \sigma_j^x$ term, which has a sign problem. Mathematically, because this problem is NP-complete, there exists a polynomial-time mapping to any other NP-complete problem.

However, the special spin glass example is equivalent to saying quantum spin glass problem is no easier to solve than the corresponding classical spin glass problem. The example is very special and the proof does not address QMC solutions of systems, such as Hubbard model without particle-hole symmetry and SU(2) frustrated quantum spin models, which are not directly associated with the difficulties of simulating classical frustrated glassy systems with complicated energy landscapes. So we cannot conclude that all sign problems are NP-hard. But from this example, at least we know that if we find a method to solve an NP-hard problem, this scheme can be used to solve QMC simulation with sign problem.

In addition, the definition $\langle s \rangle = Z/Z'$ can give us some other information. Just write it in zero-temperature limit

$$\langle s \rangle_R = \frac{Z}{Z^R} = \frac{g e^{-\beta E_0}}{g^R e^{-\beta E_0^R}}, \quad (19)$$

where g and g^R are the ground state degeneracy of system Z and reference system Z^R , while E_0 and E_0^R are the ground energy of systems Z and Z^R . This means the expectation value $\langle s \rangle_R$ can be used to read g, E_0 for finite size systems, if we engineer the reference system with known g^R and E_0^R .

For spin system case, if the systems Z and reference system Z^R have the same ground state, and the ground is in the set of QMC computational basis, one can see the reduction of the sign problem at low-temperature, as shown in [Wessel et al. \(2018\)](#) and [D'Emidio et al. \(2020\)](#). For the fermion case, we can also choose a good reference system Z^R , or choose a well-known $Z' \geq Z^R$ to get the lower bound of the sign, this will be explained in section "Sign bound theory."

Now we know the definition of sign problem, then what is the sign problem related to? The collective efforts over the years have pointed out that the sign problem has multiple origins. And we will discuss the major ones below.

Sign problem is basis-dependent

First of all, the sign problem is basis-dependent. For example, if one can diagonalize the Hamiltonian matrix and calculate the eigenstates $\{|i\rangle\}$ then $H|i\rangle = \varepsilon_i|i\rangle$ and

$$\begin{aligned} \langle O \rangle &= \text{Tr}[O \exp(-\beta H)] / \text{Tr}[\exp(-\beta H)] \\ &= \sum_i \langle i|O|i\rangle \exp(-\beta \varepsilon_i) / \sum_i \exp(-\beta \varepsilon_i). \end{aligned} \quad (20)$$

There's obviously no sign problem here. Unfortunately, it is often difficult to obtain eigenstates of a quantum many-body system in the first place. Moreover, if one already has the methods to obtain all eigenstates of the system, there is then no need to perform Monte Carlo simulations.

In addition, for interacting fermion systems, different bases will bring different effects during decoupling. In a recent paper on automatic differentiation to mitigating the sign problem (Wan et al., 2020), the authors performed different decoupling at different sites $e^{-\Delta\tau U(\hat{n}_i - \frac{1}{2})(\hat{n}_i - \frac{1}{2})} = \frac{1}{2}e^{-U\Delta\tau/4} \sum_{s_i=\pm 1} e^{is_i \hat{c}_i^\dagger \sigma \cdot \mathbf{n}_i \hat{c}_i}$, where $\mathbf{n}_i = (\sin \theta_i \sin \phi_i, \sin \theta_i \cos \phi_i, \cos \theta_i)$. The choice of basis for decoupling at different sites can affect the severity of the sign problem. While for spin systems, as discussed in Eq. (19), if the ground state is a member of the computational basis, and sign-problem-free reference system have the same ground state, reduction of the sign problem at low-temperature (Wessel et al., 2018; D'Emidio et al., 2020) will be seen.

We note there exist many research works that mitigate the sign problem by basis transformation (D'Emidio et al., 2020; Shinaoka et al., 2015; Levy and Clark, 2021; Torlai et al., 2020; Hangleiter et al., 2020; Klassen et al., 2020; Marvian et al., 2019; Kim et al., 2020; Rossi, 2017; Rossi et al., 2017). However, it has also been pointed out that some sign problems turn out to be intrinsic (Hastings, 2016; Ringel and Kovrizhin, 2017; Smith et al., 2020; Golan et al., 2020) and cannot be eliminated by local unitary basis transformations.

Sign problem is related to Pauli exclusion principle

From the point of view of world-line Monte Carlo, the exchange of fermions in the world-line will bring a minus sign, which arises from the Pauli exclusion principle. A simple such process is shown in Fig. 4 and can be derived as

$$\begin{aligned} \langle \psi_1 | \hat{c}_1^\dagger \hat{c}_4 \hat{c}_3^\dagger \hat{c}_2 \hat{c}_4^\dagger \hat{c}_3 \hat{c}_2^\dagger \hat{c}_1 | \psi_1 \rangle &= \langle \psi_1 | \hat{c}_4 \hat{c}_3^\dagger \hat{c}_2 \hat{c}_4^\dagger \hat{c}_3 \hat{c}_2^\dagger \hat{c}_1 | \psi_1 \rangle \\ &= \langle \psi_1 | \hat{c}_4 \hat{c}_3^\dagger \hat{c}_4^\dagger \hat{c}_3 (1 - \hat{n}_2) \hat{n}_1 | \psi_1 \rangle \\ &= -\langle \psi_1 | (1 - \hat{n}_4) \hat{n}_3 (1 - \hat{n}_2) \hat{n}_1 | \psi_1 \rangle \\ &= -\langle \psi_1 | \psi_1 \rangle. \end{aligned} \quad (21)$$

Sign problem is related to geometric frustration

Similarly, frustrated spin or boson systems often have sign problem. For example, if we consider a boson (spin) system of three sites

$$\hat{H} = (\hat{b}_2^\dagger \hat{b}_2 + \hat{b}_2^\dagger \hat{b}_3 + \hat{b}_3^\dagger \hat{b}_1) + \text{h.c.} \text{ or } \hat{H} (\hat{S}_1^+ \hat{S}_2^- + \hat{S}_2^+ \hat{S}_3^- + \hat{S}_3^+ \hat{S}_1^-) + \text{h.c.} \quad (22)$$

The weight is negative for the following configuration (where $|i\rangle$ means i -th site occupied state)

$$\langle 1 | e^{-d\beta \hat{H}} | 2 \rangle \langle 2 | e^{-d\beta \hat{H}} | 3 \rangle \langle 3 | e^{-d\beta \hat{H}} | 1 \rangle, \text{ contribution} = (-1)^3 d\beta^3. \quad (23)$$

However, frustration does not necessarily mean there must be a sign problem. A clever choice of basis can make the QMC simulation sign-problem free. As discussed in section "Stochastic series expansion," there is no sign problem for some bilayer frustrated models (Alet et al., 2016; Ng and Yang, 2017; Honecker et al., 2016; Stapmanns et al., 2018; StefanWessel et al., 2017). Inspired by these works and considering the model that has the same ground state as the above model, one can extend the simulation basis from spin to singlet-triplet or even plaquette bases, and recently there is progress in such cases by means of changing the simulation basis from spin to bond or even plaquette (Wessel et al., 2018; D'Emidio et al., 2020) to reduce the sign problem in the QMC simulation for 2D antiferromagnetic Shastry-Sutherland spin model.

Sign problem is related to Aharonov-Anandan phase

For DQMC, the sign problem is thought to be related to the topological properties of the configurations (Iazzi et al., 2016). One can define the weight as

Fig. 4 An example of a configuration where particle exchange leads to negative weights. The dots represent particle occupation, and bold lines are world lines.

$$W(C_i) = \det \left[1 + e^{\beta\mu} \mathcal{T} \exp \int_0^\beta d\tau H^{\text{aux}}[C_i(\tau)] \right], \quad (24)$$

then define

$$G(\tau; \beta) = \mathcal{T} \exp \int_\tau^{\tau+\beta} d\tau' H^{\text{aux}}[C_i(\tau')] \quad (25)$$

the corresponding eigenvalue and eigenstate are: $G(\tau; \beta) |\phi_n(\tau)\rangle = \lambda_n |\phi_n(\tau)\rangle$. Now one finds the weight is

$$W(C_i) = \prod_n (1 + \lambda_n e^{\beta\mu}), \quad (26)$$

by defining $\lambda_n = e^{i\theta_n} \omega_n$ and $e^{i\theta_n} = \prod_{\tau=0}^\beta \langle \phi_n(\tau + d\tau) | \phi_n(\tau) \rangle$. These phases $e^{i\theta_n}$ are imaginary time versions of the Aharonov-Anandan (AA) phase. If we take $\beta \rightarrow \infty$, which means the adiabatic limit, then the eigenstate $|\psi_n(\tau)\rangle = \lim_{\beta \rightarrow \infty} |\phi_n(\tau)\rangle$ and the weights is $\exp[-\int_0^\beta \varepsilon_n(\tau) d\tau]$, where $\varepsilon_n(\tau)$ is eigenvalue of $H^{\text{aux}}(\tau)$. Now $e^{i\theta_n}$ becomes a Berry phase of the instantaneous eigenstates $|\phi_n(\tau)\rangle$.

This analogy gives us a new perspective on the sign problem, but it doesn't help to mitigate it. In the next section, we will discuss an understanding and practical implementation scheme to cure, ease and make use of the sign problem.

How to cure, ease and make use of the sign problem

There are no general methods how to reduce the exponential computation complexity introduced by the sign problem. There are, nevertheless, different solutions for different physical systems. We note only the recent *Sign bound theory* has pointed out a generic direction (Zhang et al., 2021). Below, we select a few important cases and explain their usages.

Symmetry

In DQMC for interacting fermion models, where $H = H_K + H_I$, H_K is the kinetic energy part and H_I is the part of the interaction after decoupling (Congjun and Zhang, 2005), if there exists an anti-unitary operator T , such that

$$TH_K T^{-1} = H_K, TH_I T^{-1} = H_I, T^2 = -1. \quad (27)$$

then for the eigenvalues λ_i of matrix $I + B(\beta, 0)$, where $B(\beta, 0)$ is defined in Eq. (15), we know $\prod \lambda_i$ is real and positive number. The proof is simple. If $(I + B) |\Psi_i\rangle = \lambda_i |\Psi_i\rangle$ then $T |\Psi_i\rangle$ is also an eigenstate of matrix $(I + B)$ with eigenvalue λ_i^* . That is, the eigenvalues λ_i and λ_i^* come in pairs, and the weight $\det(I + B) = \prod |\lambda_i|^2 \geq 0$. The orthogonality of the two eigenstates is trivial: $\langle \Psi_i | T \Psi_i \rangle = \langle \Psi_i | T^\dagger T T |\Psi_i\rangle^* = -\langle \Psi_i | T^\dagger |\Psi_i\rangle^* = -\langle T \Psi_i | \Psi_i \rangle^* = -\langle \Psi_i | T \Psi_i \rangle = 0$. The overlap of the two states is zero.

In practice, one usually divides the configurational weight of the original problem into two parts according to the degrees of freedom, such as the spin up and down, then performs a unitary transformation to show the two parts of the weights are either the same real number or complex conjugate with each other, such that their product is positive definite. For example, the Hubbard model at half-filling, if $U > 0$, $e^{-\Delta\tau \hat{H}_U} = \gamma \sum_{s=\pm 1} e^{zs(\hat{n}_\uparrow + \hat{n}_\downarrow - 1)}$ where $\gamma = \frac{1}{2} e^{\Delta\tau U/4}$, $\cosh(\alpha) = e^{-\Delta\tau U/2}$, and α is an imaginary number. Now, the unitary transformation is the particle-hole transformation,

$$\begin{cases} \hat{c}_{i\downarrow}^\dagger \rightarrow (-1)^i \hat{c}_{i\downarrow} \\ \hat{c}_{i\downarrow} \rightarrow (-1)^i \hat{c}_{i\downarrow}^\dagger. \end{cases} \quad (28)$$

and

$$\alpha \text{ is an imaginary number} \rightarrow \begin{cases} \alpha(\hat{n}_{i\uparrow} + \hat{n}_{i\downarrow} - 1) \xrightarrow{PH \text{ for spin-down}} \alpha s_i(\hat{n}_{i\uparrow} - \hat{n}_{i\downarrow}) \\ e^{zs_i(\hat{n}_{i\uparrow} + \hat{n}_{i\downarrow} - 1)} \xrightarrow{PH \text{ for spin-down}} e^{zs_i(\hat{n}_{i\uparrow} - \hat{n}_{i\downarrow})}. \end{cases} \quad (29)$$

Since α is an imaginary number, it's clear to see that after such a particle-hole transformation, spin up and down parts are complex conjugated to each other.

In addition to particle-hole symmetry, other symmetries such as $C_2T + C_2P$ symmetries (Xu et al., 2021a; Johannes et al., 2021) may also make the system sign-free. In short, we want to find an anti-unitary transformation that makes the system invariant, or to apply a unitary transformation, then the weights are divided into two parts that are obviously complex conjugate to each other. Such a scheme has been widely used in the DQMC solution of interaction driven topological phase transitions, such as in the Kane-Mele Hubbard model (Hohenadler et al., 2012; Meng et al., 2014).

Split orthogonal group, Majorana representation and Majorana positivity

Subsequently, people have made more in-depth studies on sign of determinants of matrices. For example, there is a theorem (Wang et al., 2015):

If M belongs to the split orthogonal group $O(n, n)$, then

$$\det(I + M) \begin{cases} \geq 0, & \text{if } M \in O^{++}(n, n), \\ \leq 0, & \text{if } M \in O^{--}(n, n), \\ 0, & \text{otherwise,} \end{cases} \quad (30)$$

where the split orthogonal group $O(n, n)$ is formed by all $2n \times 2n$ real matrices that preserve the metric $\eta = \text{diag} \left(\underbrace{1, \dots, 1}_n, \underbrace{-1, \dots, -1}_n \right)$, $M^T \eta M = \eta$. Split orthogonal group $O(n, n)$ means that if we write the matrix M in the block form like: $M = \begin{pmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{pmatrix}$, then we have $|\det(M_{11})| \geq 1$ and $|\det(M_{22})| \geq 1$. And we use the notation $O^{\pm\pm}(n, n)$ to classify the four components of $O(n, n)$ by considering the signs of $\det(M_{11})$ and $\det(M_{22})$.

Since the fermion sign problem is related to the basis of decoupling, it can be found that some models translated to Majorana representation are sign-problem free (Li et al., 2015, 2016; Li and Yao, 2019). Majorana representation is turning fermions into Majorana fermions

$$\hat{c}_i = \frac{1}{2}(\gamma_i^1 + i\gamma_i^2), \quad \hat{c}_i^\dagger = \frac{1}{2}(\gamma_i^1 - i\gamma_i^2). \quad (31)$$

These findings inspired research on Majorana reflection positivity or the Majorana Kramers positivity (Wei et al., 2016). One can write the H_0 and decoupled Hamiltonian under the Majorana representation: $H_{bl} = \gamma^T V \gamma$. Then.

(a) if V is a Majorana reflection positive kernel, it can be represented as

$$V = \begin{pmatrix} A & iB \\ -iB^T & A^* \end{pmatrix}, \quad (32)$$

where A and B are $N \times N$ matrices. A is complex antisymmetric matrix and B is a Hermitian matrix. Or,

(b) if there exist two transformation operators S and P such that

$$\begin{aligned} S^T V S &= V^*, \\ P V P^{-1} &= V, \end{aligned} \quad (33)$$

where S is a real antisymmetric matrix and P is a symmetric or antisymmetric Hermitian matrix, and we need P anticommutes with S . There is no sign problem in the DQMC simulation.

In Xu et al. (2019b), there is a similar discussion on the sign problem related to the structure of the fermion determinant. It is proven that if $D \in \text{SU}(n, m)$, then $\det(I_{n+m} + D) \in \mathbb{R}$, where $\text{SU}(n, m)$ is a pseudo-unitary group. Such condition is used to guarantee the DQMC simulation for $\text{U}(1)$ gauge field coupled to Dirac fermions in $(2+1)\text{d}$, a fundamental problem for both high-energy physics and condensed matter physics related to quantum electrodynamics and deconfined quantum criticalities, is sign-problem free (Xu et al., 2019b; Wang et al., 2019; Janssen et al., 2020).

Sign bound theory

As discussed in section “What is the sign problem?,” for systems with sign problems, we can usually sample them by reweighting and the average sign is usually $\langle s \rangle = Z/Z' \sim e^{-\beta N \Delta f}$. However, the difference of free energy Δf between the reference system Z' and the system Z is not necessarily a constant with little change, but may be a quantity depending on the system size $N = L^d$ and inverse temperature $\beta = \frac{1}{k_B T}$.

In some systems, we find that in the zero-temperature limit, the sign does not decay exponentially with respect to size L but rather decays algebraically (Ouyang and Xu, 2021; Zhang et al., 2021), implying that Δf could be a logarithmic function of L . In fact, in the zero-temperature limit, the mean of the signs is $\langle s \rangle_R = \frac{Z}{Z^R} = \frac{g e^{-\beta E_0}}{g^R e^{-\beta E_0^R}}$ as given in Eq. (19). We can choose a good reference system Z^R , which has the same ground state energy $E_0^R = E_0$ with Z . Then the mean of the signs is $\langle s \rangle_R = g/g^R$, which is only related to the ratio of ground state degeneracy. And as shown in the cases below, in a few common situations, such as the lattice model for quantum Moiré materials in momentum space (Xu et al., 2021a,b; Zhang et al., 2021; Pan et al., 2022) and extended Hubbard model in real space (Ouyang and Xu, 2021; Da Liao et al., 2022, 2021; Liao et al., 2021), the ground state degeneracy is a polynomial function of the size of the system.

Even if most of the time we cannot find such a perfect Z^R , we can still consider the upper bound on the value of Z^R , which means if we know $Z^R \leq C$, then in the zero temperature limit we can get a lower bound of the sign: $\langle s \rangle_R = \frac{Z}{Z^R} \geq \frac{g e^{-\beta E_0}}{C}$. This is the *Sign bound theory* (Zhang et al., 2021). Two cases of the theory will be shown below. In case 1: $Z^R = g^R e^{-\beta E_0^R} \leq \sqrt{g' e^{-\beta E_0'}}$ and $E_0'/2 = E_0$ such that $\langle s \rangle_R = \frac{Z}{Z^R} \geq \frac{g e^{-\beta E_0}}{\sqrt{g' e^{-\beta E_0'}}} = g/\sqrt{g'} e^{-\beta(E_0 - E_0'/2)} = g/\sqrt{g'}$, and in case 2: $Z^R = g^R e^{-\beta E_0^R} \leq g' e^{-\beta E_0'}$ and $E_0' = E_0$ such that $\langle s \rangle_R = \frac{Z}{Z^R} \geq \frac{g e^{-\beta E_0}}{g' e^{-\beta E_0}} = g/g' e^{-\beta(E_0 - E_0')} = g/g'$. If we succeed in finding such an upper bound on Z^R which can cancel out the $e^{-\beta E_0}$

term in the denominator, then the lower bound of the sign is just a function of the ground state degeneracy. If the ground state degeneracy is a polynomial function of the size of the system, then we can obtain a lower bound of the average sign decay with the system size algebraically.

Case 1

For example, we choose $Z^R = \sum_{\{l\}} P(\{l\}) |\mathcal{R}(D(\{l\}))| \equiv \langle |\mathcal{R}(D)| \rangle$ and $Z' = \sum_{\{l\}} P(\{l\}) |D|^2(\{l\}) \equiv \langle |D|^2 \rangle$, where $Z = \sum_{\{l\}} P(\{l\}) D(\{l\}) \equiv \langle D \rangle = \langle \mathcal{R}(D) \rangle$. Here $D(\{l\})$ is the determinant term in weight, and $P(\{l\})$ is a normalized probability distribution. Because $\langle |\mathcal{R}(D)| \rangle \leq \sqrt{\langle |D|^2 \rangle}$ then $\langle s \rangle = \frac{Z}{Z^R} \geq \frac{g e^{-\beta E_0}}{\sqrt{g' e^{-\beta E'_0}}} = g/\sqrt{g'} e^{-\beta(E_0 - E'_0/2)} = g/\sqrt{g'}$, if $E_0/2 = E'_0$.

The twisted-bilayer-graphene (TBG) models, projected to the flat bands, belong to such a case (Xu et al., 2021a; Pan et al., 2022). In the chiral limit, the Hamiltonian only has density-density interaction in momentum space

$$H = \sum_{q \neq 0} V(q) \rho_{-q} \rho_q = \sum_{q \neq 0} V(q) \rho_q^\dagger \rho_q, \quad (34)$$

where $\rho_q = \sum_{i,j} (\lambda_{i,j}(q) \hat{c}_i^\dagger \hat{c}_j - \frac{1}{2} \mu_q)$.

If we set λ as random number and $\mu_q = 0$, and there is no other symmetry, then $E_0 = E'_0/2$. For ground state degeneracy, it's easy to know $g = 2$ and $g' = N + 3$, by introducing a raising operator $\Delta^\dagger = \sum_i c_i^\dagger, \dots$. Then at low temperature, $\langle s \rangle \geq 2/\sqrt{N+3}$ (as shown in Fig. 5(a)).

We consider single valley/spin two band ($m, n \in \{1, -1\}$) TBG model at half-filling and chiral limit, which means $\lambda_{i,j,m,n}(q) = m \cdot n \cdot \lambda_{i,j,m,n}(q)$ and $\mu_q \neq 0$. Similarly, we still have $E_0 = E'_0$ and $g = 2$, and now $g' = (N+1)^2 + 2$. Then at low temperature, $\langle s \rangle \geq 2/\sqrt{(N+1)^2 + 2}$ (as shown in Fig. 5(b)).

Case 2

If we consider the real space extended Hubbard model (Ouyang and Xu, 2021; Liao et al., 2021; Da Liao et al., 2021), which also offers the description of the TBG systems once the interactions are projected to the flat bands with truncation

$$\hat{H} = U \sum_{\square} (\hat{Q}_{\square} + \alpha \hat{T}_{\square} - v)^2, \quad (35)$$

where $\hat{Q}_{\square} = \frac{1}{3} \sum_{\sigma,\tau} \sum_{l=1}^6 \hat{c}_{R+\delta_l,\sigma,\tau}^\dagger \hat{c}_{R+\delta_l,\sigma,\tau} - 4$, $\hat{T}_{\square} = \sum_{\sigma,\tau} \sum_{l=1}^6 [(-1)^l \hat{c}_{R+\delta_{l+1},\sigma,\tau}^\dagger \hat{c}_{R+\delta_l,\sigma,\tau} + \text{h.c.}]$, v is used to control filling, σ, τ are spin and valley indexes, $R + \delta_l$ represents site l in a single R hexagon and U, α is real number coming from the overlap of Wannier functions on the Moiré scale.

Here, we choose $Z' = \sum_{\{l\}} P(\{l\}) |D|(\{l\}) \equiv \langle |D| \rangle$, still $Z^R = \sum_{\{l\}} P(\{l\}) |\mathcal{R}(D(\{l\}))| \equiv \langle |\mathcal{R}(D)| \rangle$ and $Z = \sum_{\{l\}} P(\{l\}) D(\{l\}) \equiv \langle D \rangle = \langle \mathcal{R}(D) \rangle$. Because $\langle |\mathcal{R}(D)| \rangle \leq \langle |D| \rangle$ then $\langle s \rangle = \frac{Z}{Z^R} \geq \frac{g e^{-\beta E_0}}{g' e^{-\beta E'_0}} = g/g' e^{-\beta(E_0 - E'_0)} = g/g'$. Similarly, we still have $E'_0 = E_0$. It can be computed from tensor Young tableau method that, at $v = \pm 2$, $g = (N+3)(N+2)(N+1)/6$, and at $v = 0$, $g' = (N+3)(N+2)^2(N+1)/12$ (Zhang et al., 2021). Then at low temperature, $\langle s \rangle \geq g/g' = 2/(N+2)$ (as shown in Fig. 5(c)).

For the model we mentioned above and its reference system, the exponential decay part cancels out, and we can easily calculate the ground state degeneracy. As shown in Fig. 5, numerically we also see that at very low temperatures the average sign decays polynomially.

Fig. 5 The average sign for three different cases according to the *sign bound theory*. All measurement are carried out at a average sign converged temperature. The errorbars in QMC data are smaller than the symbol size. (a) momentum space case, now λ is randomly set, and the red line gives us the lower bound $\langle s \rangle \geq 2/\sqrt{N+3}$. Here $N = 18, 32, 50, 72, 98, 128, 162$. Fitting line $\propto N^{-0.23}$. (b) momentum space case, we consider $v = 0$ single valley/spin TBG model in chiral limit, and the red line gives us the lower bound $\langle s \rangle \geq 2/\sqrt{(N+1)^2 + 2}$. $N = 9, 16, 25, 36, 49$ and $T = 0.91$ meV. Fitting line $\propto N^{-0.70}$. (c) For real space TBG model, the red line lower bound is $\langle s \rangle \geq 2/(N+2)$ and $N = 18, 72, 162, 288, 450, 648, 882$. The parameters of QMC are detailed in (Ouyang and Xu, 2021). Fitting line $\propto N^{-0.98}$.

Lefschetz thimble

This is also a method that can be used to cure or reduce the sign problem in lattice fermion QMC simulations (Ulybyshev et al., 2020; Alexandru et al., 2020; Cristoforetti et al., 2013; Fukuma et al., 2019; Mukherjee and Cristoforetti, 2014; Mukherjee et al., 2013; Mooney et al., 2021; Mishchenko et al., 2021; Körner et al., 2020), here we only briefly outline its main idea.

For computing the expectation value $\langle O[x] \rangle$ in Monte Carlo sampling on the configuration space $[x]$, we have

$$\begin{aligned} \langle O[x] \rangle &= \frac{1}{Z} \int dx e^{-S[x]} O[x] \\ &= \frac{\int dx e^{-S_R[x]} e^{-iS_I[x]} O[x]}{\int dx e^{-S_R[x]} e^{-iS_I[x]}} \\ &= \frac{\int dx e^{-S_R[x]} e^{-iS_I[x]} O[x]}{\int dx e^{-S_R[x]}} \bigg/ \frac{\int dx e^{-S_R[x]} e^{-iS_I[x]}}{\int dx e^{-S_R[x]}} \\ &= \frac{\langle e^{-iS_I} O \rangle_R}{\langle e^{-iS_I} \rangle_R}, \end{aligned} \quad (36)$$

where R and I means real and imaginary parts of action $S[x]$. And $\langle \cdot \rangle_R$ is defined as $\langle O \rangle_R = \frac{\int dx e^{-S_R[x]} O}{\int dx e^{-S_R[x]}}$.

If the action $S[x]$ is analytic for all $x \in \mathbb{C}^n$, its saddle points are nondegenerate and Eq. (36) is convergent, then Morse theory (Banyaga and Hurtubise, 2004; Witten, 2010, 2011) told us these integrals can be evaluated using the steepest descent cycles $\mathcal{J}_\sigma$. They are called Lefschetz thimbles, which means we can replace the integration over the real domain $\mathbb{R}^n$ with that over curved complex n -dimensional manifolds $\mathcal{J}_\sigma$

$$\int_{\mathbb{R}^n} dx e^{-S(x)} = \sum_{\sigma} n_{\sigma} \int_{\mathcal{J}_{\sigma}} dx e^{-S(z)}, \quad (37)$$

where the Lefschetz thimbles $\mathcal{J}_\sigma$ are the union of all solutions of the gradient flow equations

$$\frac{dz(\tau)}{d\tau} = -\frac{\partial \bar{S}}{\partial z}, \quad (38)$$

and it starts from the corresponding saddle point z_σ , which means $\lim_{\tau \rightarrow \infty} z(\tau) = z_\sigma$. Here σ is the index for different saddle point/Lefschetz thimbles, τ is a parameter and the overline represents complex conjugation, and saddle point is the point on the surface of S where the derivatives in orthogonal directions are all zero, but is not a local extremum. While the thimbles always end inside regions of stability, dual thimbles (anti-thimbles) $\mathcal{K}_\sigma$ are also such solutions at a given saddle point $\lim_{\tau \rightarrow -\infty} z(\tau) = z_\sigma$ and end inside regions of instability. We can make an analogy between the dual thimble and the contour of the steepest ascent, as we did with the thimble and the contour of the steepest descent. And n_σ are intersection numbers (which decide the contribution of a particular saddle point z_σ to the partition function) of hypersurface generated by the paths of steepest ascent duals $\mathcal{K}_\sigma$ and the original region of integration $\mathbb{R}^n$

$$n_\sigma = \langle \mathcal{K}_\sigma, \mathbb{R}^n \rangle. \quad (39)$$

The important point of such construction is: $\text{Im}[S]$ is constant on Lefschetz thimbles (mod 2π), which means there is no sign problem on each thimble. The ratio of weights in the same thimble must be a positive real number, since the phase of the weight is the same.

Let's take a trivial 1d case for the purpose of illustration (Kanazawa and Tanizaki, 2015; Bharathkumar and Joseph, 2020)

$$\int_{\mathbb{R}+i\epsilon} dx \frac{1}{x} e^{-x^2/2} = \sum_{\sigma} n_{\sigma} \int_{\mathcal{J}_{\sigma}} dz e^{-S(z)}, \quad (40)$$

which corresponds to the case $S[z] = \log z + z^2/2$. The two critical points of this action are: $z_1 = i$, $z_2 = -i$. Since we know that the imaginary parts $\text{Im}[S]$ are constant on Lefschetz thimbles, then we have: $\text{Im}[S[z]]|_{\text{along } \mathbb{R}+i\epsilon} = \text{Im}[S[z_\sigma]] = i\pi/2$. Following the procedure described above we can obtain the corresponding thimbles and dual thimbles (as shown in Fig. 6), and then $\int_{\mathbb{R}+i\epsilon} dx \frac{1}{x} e^{-x^2/2} = \int_{\mathcal{J}_1} dz e^{-S(z)}$.

The Lefschetz thimbles method is commonly used to calculate the value of certain integrals and in high-energy physics and real time calculations. Recently, with the application of hybrid Monte Carlo in condensed matter, there has been a lot of work using the Lefschetz thimbles method to study common condensed matter problems which have sign problems. For example, Hubbard model on the hexagonal (honeycomb) lattice at finite chemical potential with linear system size $L = 6$ and inverse temperature $\beta = 20$, has been successfully simulated with Lefschetz thimbles method in DQMC (Ulybyshev et al., 2020; Körner et al., 2020).

Fig. 6 A schematic plot of thimbles and dual thimbles. Here the black dots are saddle points $z_{1,2}$, while the solid blue/purple lines correspond to thimbles and the dotted red/yellow lines correspond to dual thimbles. And the arrows show the directions of the flows. See intersection numbers of dual thimbles and $\mathbb{R} + ik$, we know $n_1 = 1$, $n_2 = 0$.

Conclusion

In this article, we give a pedagogical overview on the origin of the sign problem in various quantum Monte Carlo simulation techniques, ranging from the world-line and stochastic series expansion Monte Carlo for boson and spin systems to the determinant and momentum space quantum Monte Carlo for interacting fermions. We have elaborated on the definition of the sign problem and its possible origins, including the Pauli exclusion principle, geometric frustration and the lack of symmetry requirements, etc. In addition, we also point out the sign problem is actually basis-dependent and summarize established ways to ensure that some models are free of sign problems such as checking symmetry and Majorana positivity. We explain what to do when there is a sign problem in general: reweighting, and how to reduce the severity of sign problems, in particular that based on the properties of the finite size partition functions, the recent *sign bound theory* could distinguish when the bounds have the usual exponential scaling, and when they are bestowed with an algebraic scaling at the low temperature limit. Fermionic QMC simulations with such algebraic sign problems have been successfully carried out for extended Hubbard-type and quantum Moiré lattice models.

Acknowledgments

We thank Xu Zhang, Weilun Jiang, Yuan Da Liao and Xiao Yan Xu for insightful discussions and fruitful collaborations on related topics over the years. GPP and ZYM acknowledge the support from the Research Grants Council of Hong Kong SAR of China (Grant Nos. 17303019, 17301420, 17301721 and AoE/P-701/20), the Strategic Priority Research Program of the Chinese Academy of Sciences (Grant No. XDB33000000), the K. C. Wong Education Foundation (Grant No. GJTD-2020-01) and the Seed Funding “QuantumInspired explainable-AI” at the HKU-TCL Joint Research Centre for Artificial Intelligence. We thank the Information Technology Services at the University of Hong Kong and the Tianhe platforms at the National Supercomputer Centers for their technical support and generous allocation of CPU time.

Abstract

When confined to lower dimensions, electrons often start behaving in new and unexpected ways. This is particularly striking in one dimension (1D), for here, both individual, as well as collective, properties can start to emerge, making these systems a very rich playground on which single- and many-body physics can be studied. In this chapter, we introduce the field of one-dimensional electronic systems by discussing a series of results in fundamental physics obtained over the past few decades using semiconductor devices at low temperatures. We start by reviewing the transport properties of these systems and, specifically, the observation of conductance quantization in 1D. We then focus on a series of interaction effects that have been observed in more recent years, from the well-known “0.7 structure” to the Tomonaga-Luttinger liquid and its more recent nonlinear counterparts.

Key points

This chapter describes the one-dimensional electronic system with particular emphasis on its experimental realization using semiconducting devices. It aims to provide a first introduction to the subject by highlighting some of the early work, as well as more recent developments in the field. The topics covered are:

- the experimental realization of a quasi-1D system;
- its subbands, eigenstates and conductance quantization in units of $2e^2/h$;
- the “0.7 structure,” which is a feature below the lowest conductance plateau and requires an explanation in terms of many-body physics;
- the Tomonaga-Luttinger liquid, which is the exact many-body description of a true 1D system at low energies, with particular emphasis on the observation of spin-charge separation and zero-bias anomaly;
- the nonlinear Luttinger liquid, which tries to describe interacting 1D systems beyond the low-energy limit, including recent developments on 1D “replica” modes and separate Fermi seas for spin and charge.

Introduction

How do electrons move inside solids? Do they flow, like a stream down a hill, or instead remain static, close to their atomic hosts? Furthermore, when in the presence of other electrons, do they behave collectively or are they instead, for the most part, unaware of the presence of each other? The challenge posed by these questions is the bedrock of modern-day condensed-matter physics, and to answer them we must first understand how and where electrons are moving in the first place.

The world is three-dimensional, but we mainly live on a two-dimensional flat surface, and sometimes a flow is confined to a single dimension, a line, for example, in rivers and roads. In a conducting solid, electrons flow to carry a current. But a wire is huge on the scale of the distance an electron can move before being scattered, so it is not usually 1D.

With the advent of nanoelectronics, we can grow and pattern materials that are so pure that scattering can almost be ignored on the length scales of the microscopic wires in which we can channel electrons. We then start to see extraordinary new phenomena, where electrons act as waves and form standing waves across the wire, showing beautiful, equally spaced steps in the inverse of the resistance, which is called the conductance.

However, electrons are charged particles and repel each other, so interactions should be important. Remarkably, these interactions are usually hidden because excitations of a collection of interacting electrons actually behave like single electrons. In 1D, on the other hand, this is not the case—as on a single-track road, cars (or electrons) cannot get past each other. So, instead, waves of charge and spin travel along the queues of electrons, more like sound waves, and these can be detected in special experiments, as we will now discuss.

The mesoscopic regime

The first attempt at describing charge transport inside solids (and specifically, metals) led to what came to be known as the Drude model (Drude, 1900; Ashcroft and Mermin, 1976). The goal was to explain what was empirically already established as Ohm's law, that is, that the current through a conductor is directly proportional to the voltage applied along it, with the proportionality constant defining the resistance, R , of a given material. Drude managed to explain this observation in terms of scattering of electrons against a static background of ions which, macroscopically, gave rise to an electrical resistance.

Drude's model was essentially an application of the kinetic theory of gases, whereby the electrons inside a conductor were seen as bouncing about like billiard balls and following the laws of classical Newtonian mechanics. However, once the theory of Quantum Mechanics was developed in the 1920s, it became clear that subatomic particles such as electrons should be treated as waves (or wave functions), rather than simple point-like particles. Bloch showed that the periodic potential from the crystal lattice in a solid had the effect of combining all the quantum-mechanical states on each atom into a set of waves that modulate the wave functions on each atom and broaden their quantized energy levels into "bands" (Bloch, 1929). We generally say that these plane "Bloch" waves have wavelength $2\pi/k$, where k is called the wavenumber (or, including the direction, $\mathbf{k}$, the wavevector).

Having established the existence of electronic bands, however, one must now question how to populate the available states. For simplicity, let us assume that no interactions are present, that is, everything can be described in terms of plane waves. Because electrons are spin-1/2 particles, they are fermions, meaning that they follow Fermi-Dirac statistics. A well-known consequence of this is the Pauli exclusion principle. Put simply, this prevents any two fermions from occupying the same state, unless they differ in spin direction ("up" or "down"). This has profound consequences in the way electrons are distributed energetically inside a crystal, and leads us to the concept of a Fermi surface, see Fig. 1. At zero temperature, all the states are filled with electrons, starting with the lowest energy until all the available electrons have been accommodated. The Fermi energy E_F lies between the energy of this highest occupied state and the next, empty, state.

In three dimensions (3D), the Fermi surface for a system of free electrons is a simple sphere or, in two dimensions (2D), a circle. Here, the most energetic state defines the Fermi energy, $E_F = \hbar^2 k_F^2 / 2m_e$, where k_F is the Fermi wavevector and m_e the free-electron mass. In one dimension (1D), however, things start to change, as the Fermi "surface" now is simply two degenerate points at $\pm k_F$! As we will see later, this drastically affects the dynamics of electrons when confined to 1D. The principal effect of the presence of band structure is to change m_e to the "effective" mass m^* , which is a constant near the extremities of each band. Generally speaking, however, m^* tends to be a little less than m_e in semiconductors (e.g., $0.067 m_e$ in GaAs).

The implicit assumption behind all these pictures is that the electrons can be treated as occupying single-particle states, each with a different wavevector $\mathbf{k}$, in other words neglecting the possibility of many-body effects. Similarly, by treating the electrons as purely classical point-like particles, or quantum-mechanical "wave packets" with well-defined momentum and some idea of their position, collisions are taken to be instantaneous or, at least, much shorter than the average time it takes for them to occur. This means that, when in the presence of some sort of physical gradient, (e.g., temperature, electric or magnetic fields, stress, etc.), transport across a system of characteristic length $L \gg \ell$ is typically *diffusive*, with electrons behaving as if undergoing a random walk of typical step size ℓ . Alternatively, if $L \ll \ell$, then we enter into the *ballistic* regime, meaning that electron motion can only be altered by collision with a boundary. In the middle between these two limits, we enter the *mesoscopic* regime, where one cannot average over scattering sites, such as impurities, and each "device" may behave slightly differently.

In order for mesoscopic or ballistic effects to be observed, electrons must be confined to sufficiently small structures and/or cooled to sufficiently low temperatures. The field of quantum transport concerns, generally speaking, the study of electron flow inside materials and devices confined in at least one of the dimensions to a nanometer length-scale (< 100 nm) where an electron wave function comes back on itself and interferes constructively, forming one of a set of standing waves with particular allowed energies, or increasing or decreasing the transmission through the device as interference between different paths the wave can take changes from constructive to destructive.

Technological improvements have allowed for the fabrication of structures where the number of dimensions to which the electron gas is confined is two (e.g., semiconductor quantum wells, ultra-thin films, graphene), one (e.g., quantum wires, carbon

Fig. 1 Free electrons in different dimensions. The Fermi surface of a system of free electrons is a sphere in three dimensions (a), a circle in two dimensions (b), and merely two degenerate points in one dimension (c). Here, k_F is the Fermi wavevector, defined through $E_F = \hbar^2 k_F^2 / 2m_e$, where E_F is the Fermi energy and m_e the free-electron mass. Made by Pedro Vianez.

nanotubes, edge states), or even zero (e.g., quantum dots). In all these systems the key requirement is for each of the confining dimensions to be of the order, if not smaller, of the de Broglie wavelength of the electrons, given by $\lambda = h/p$, where h is Planck's constant and p the electron's momentum.

In this chapter we focus on a type of system where electrons are confined in all but one dimension. As we will see, such 1D constrictions not only give rise to quantized conductance $G(=1/R)$ but also strongly-correlated states which break away from the single-particle picture and the traditional Fermi-liquid-like behavior typically observed at higher dimensions (Giuliani and Vignale, 2005).

Experimental realization of a (quasi-)1D system and quantization of conductance

Historically, the first materials to be investigated were naturally bulk (i.e., three-dimensional, 3D) crystals, for these were already readily accessible. These were followed by two-dimensional (2D) semiconducting quantum wells in the second half of the 20th century, mostly notably GaAs/AlGaAs heterostructures, which led to Nobel-Prize-winning discoveries like the integer (Klitzing et al., 1980) and fractional (Tsui et al., 1982) quantum Hall effects. The ability to trap and manipulate individual electrons was also achieved via quantum dots, that is, zero-dimensional (0D) structures, with Coulomb blockade leading to clear demonstrations of quantization of the electrical current (Kouwenhoven et al., 1991; Blumenthal et al., 2007). One-dimensional (1D) systems, on the other hand, have always remained elusive, for these are not only difficult to probe experimentally, but also more prone to disorder effects.

A popular way of realizing a 1D system uses a pair of split gates (Thornton et al., 1986), see Fig. 2. Here, two gates with a narrow gap in between are patterned on the surface of a material containing a two-dimensional electron gas (2DEG), for instance a high-purity semiconducting GaAs/AlGaAs heterostructure grown by molecular-beam epitaxy (MBE). As a progressively more negative voltage is applied to both gates, the electron gas beneath becomes fully depleted and the depletion region spreads sideways into the gap, reducing the width of the remaining narrow strip of electrons below the ungated region until this channel pinches off completely. If there is no scattering within the width of the channel, a standing wave forms as the component of the wave across the channel interferes constructively with itself after being reflected at each edge. This gives rise to modes, like the harmonics on a violin string, each with a fixed energy E_0^n for mode n . The motion along the channel is still unconstrained, so the total energy is the sum of the corresponding kinetic energy and E_0^n , and the set of such states is called a "subband." As the channel is squeezed, the modes become spaced out in energy enough that a certain integer number N of subbands is occupied (below the Fermi energy E_F), without thermal excitation into the next subband, so $E_0^N < E_F < E_0^{N+1}$.

If we now consider the current dI traveling along this channel at energy E in a small energy range dE , we can calculate this current very simply, using the well-known formula $dI = dnAv(E)e$, where dn is the density of electrons in this energy range dE , A the cross-sectional area, $v(E)$ the electron velocity at energy E and e the electronic charge. In 1D, dnA is just the number of charge carriers per unit length between energies E and $E + dE$, which is half the product of dE , the density of states in energy $g(E)$, and the probability that a state is occupied, which is the Fermi-Dirac function $f(E_F)$, a step function broadened by temperature T . The half comes from the fact that half the states are coming from the other end of the channel and so will be considered separately. In 1D,

$$g(E) = \frac{2}{\pi} \frac{dk}{dE}$$

and the electron wave's "group" velocity

$$v(E) = \frac{1}{\hbar} \frac{dE}{dk}.$$

So, using $\hbar = 2\pi\hbar$,

Fig. 2 The split-gate device. Schematic representation of a split-gate device patterned on the surface of a semiconductor heterostructure (e.g., GaAs/AlGaAs) for creating a (quasi-)1D system. Surface Ti/Au gates (yellow) deplete the 2DEG underneath (blue) leaving a narrow channel in between the source and drain contacts (orange). From Chapter 4, Lecture Notes from the Physics of Nanoelectronic Systems Course (Internal Cambridge course).

$$dI = \frac{1}{2} \left(\frac{2}{\pi} \frac{dk}{dE} \right) \left(\frac{1}{\hbar} \frac{dE}{dk} \right) f(E - E_F) e dE$$

$$= f(E - E_F) \frac{2e}{h} dE.$$

$f(E - E_F)$ gives the distribution of occupied energy levels around the Fermi energy. At a finite temperature, even far below E_F , all the states are occupied, and far above, they are all empty. At one end of the channel, the bias V applied there (relative to the voltage at the other end) changes the energy of all the states coming from that end by $-eV$, so for current coming from that direction, the distribution function becomes $f(E - (E_F - eV))$.

The total current I is given by the integral over all energies of the current elements traveling one way along the channel minus those traveling in the opposite direction, i.e.,

$$I = \frac{2e}{h} \int_{-\infty}^{\infty} (f(E - E_F) - f(E - E_F + eV)) dE.$$

The trick for calculating this integral is to shift one distribution by eV , to line up with the other, as they are identical in shape apart from this offset in energy. That adds an amount of height 1 and width eV at the low-energy end of one function in the integrand, making the integral just equal to eV (see Fig. 3). Hence, the total current is

$$I = \frac{2e^2}{h} V.$$

Therefore, the current per unit voltage (the conductance) carried by a 1D subband does not depend on how fast electrons are traveling at E_F , nor even on how E varies with k , and is just $G_0 \equiv 2e^2/h$. When there are N subbands, the conductance is simply

$$G = I/V = Ne^2/h.$$

No theorist had dared to predict anyone would observe such a simple result before the beautiful experiments in 1988 (van Wees et al., 1988; Wharam et al., 1988)! These showed a series of steps in conductance at these values, as explained (though not predicted!) by the above calculation (Wharam et al., 1988).

A few years later, Thomas et al., using a particularly high-quality GaAs/AlGaAs heterostructure showed a very large number of quantized plateaux, see Fig. 4 (Thomas et al., 1995). The split-gate device was measured at a temperature below 100 mK. Once the 2DEG underneath the gates was depleted at around -0.6 V, a series of over 20 quantized plateaux were observed in the conductance at integer values of $2e^2/h$. One has to account for a small, constant series resistance, and the plateau accuracy is not good enough to be used as a resistance standard (unlike the plateaux in the quantum Hall effect). By briefly illuminating the sample with an LED, the carrier density is increased, moving the curve to the left and changing the series resistance, but not altering the heights of the steps, highlighting their dependence only on the fundamental constants $\hbar$ and e .

To understand the 1D subbands better, we can write down Schrödinger's equation for a quasi-1D system as

$$\left(\frac{p^2}{2m^*} + V(y) \right) \psi = E\psi, \quad (1)$$

where $V(y)$ is the transverse confining potential created by the gates, taking the channel to be infinitely long on the assumption that end effects can be neglected. Because there is translational invariance along the channel (i.e., the x -direction), the solutions will take the form $\psi_{k,n} = \exp(ik_x x) \phi_n(y)$, namely plane Bloch waves along the channel and a confined wavefunction $\phi_n(y)$ across it.

Fig. 3 The Fermi-Dirac distribution. Two Fermi-Dirac functions $f(E - E_F)$ (blue) and $f(E - (E_F - eV))$ (red), showing how they are identical apart from the offset in energy eV . The area between the two curves is the same as the area on the left created by shifting one function to line up with the other. Made by Christopher Ford.

Fig. 4 Conductance quantization in 1D ballistic channels. Here, the differential conductance G can be seen to rise in steps of $2e^2/h$ (after a series resistance has been subtracted) as the gate voltage V_g , which defines the 1D constriction, is made progressively less negative. The two curves were measured before and after the sample was illuminated briefly, which changed the carrier concentration but clearly left the step heights unchanged. Over 20 steps can be observed, implying a very clean, ballistic channel. Inset: Full conductance sweep in gate voltage, for both samples, showing both the definition and pinch-off points. Reproduced from Thomas KJ, Simmons MY, et al. (1995) Ballistic transport in one-dimensional constrictions formed in deep two-dimensional electron gases. *Applied Physics Letters* 67: 109–111, with the permission of AIP Publishing.

Fig. 5 Characterization of an electrostatically-defined 1D system. As the gate voltage V_g , which selectively depletes a 2DEG into forming an array of 1D wires, is made progressively more negative, the transition from a 2D band to multiple 1D subbands can be observed. The full dispersion is mapped by tracking the tunneling conductance to and from this system to another nearby 2DEG as a function of in-plane magnetic field B ($\propto$ momentum). From Vianez P (2022) *Semiconductor Nanodevices as a Probe of Strong Electron Correlations*. PhD thesis. University of Cambridge, reprinted with permission.

The simplest realistic example of a confinement potential is given by the well-known quantum harmonic oscillator, that is, $V(y) = 1/2m^*\omega_0^2y^2$. In this case, the solutions are given by the Hermite polynomials, with the corresponding eigenvalues being

$$E_{k_x, n} = \left(n + \frac{1}{2}\right)\hbar\omega_0 + \frac{\hbar^2 k_x^2}{2m^*}. \quad (2)$$

This is an example of the fact that, in a 1D system, the values of the kinetic energy due to motion across the channel, E_0^n , which is $(n + \frac{1}{2})\hbar\omega_0$ for a harmonic oscillator, are quantized (the first term on the right in the above equation), with the momentum along the channel remaining unconstrained, leading to bands of energies (the second term), called 1D subbands as discussed earlier, see Fig. 5 (Vianez, 2022). As mentioned above, only subbands with E_0^n below E_F are occupied. In general, the potential changes from fairly parabolic (harmonic) for the lowest subband to more like a square well with rounded edges for much higher subbands (Laux et al., 1988).

In order to observe quantized conductance, electrons must pass along the entire narrow part of the channel without being scattered backwards, that is to say, along a “ballistic” channel. Split gates patterned using electron-beam lithography must usually therefore be less than a micron long, even when using high-quality material with the fewest background impurities and a large spacer layer between the 2DEG and the donor impurities. These short channels are also often referred to as quantum point contacts (QPCs), as some were originally made narrower at one end to minimize their length (van Wees et al., 1988). Instead of doping the material to provide the conduction electrons, one can use a central gate between the split pair, positively biased to induce electrons at an interface below this middle gate. Induced channels up to 2 μm long showed good conductance plateaux (Pyshkin et al., 2000).

One also requires low-enough temperature that the lowest energy in each subband is fully occupied or not occupied at all (otherwise the quantized conductance plateaux become shorter and less flat). At low magnetic field B , the system is largely unpolarized, and the factor of 2 in G_0 arises from this spin degeneracy. At high fields, the number of plateaux should double as Zeeman spin splitting breaks the degeneracy, and this is indeed observed (Wharam et al., 1988; Graham et al., 2003).

It can also be seen in Fig. 4 that the flatness and accuracy of the plateaux decrease as the number N of occupied subbands increases with less-negative gate voltage. The subband spacing decreases as the gates confine the channel less, increasing thermal excitation and impurity scattering between subbands. But also, the first unoccupied subband does become occupied near the ends of the channel as the confinement decreases, and tunneling between these two ends can occur along the channel, so that this subband starts being transmitted before the previous one has ceased to be partially reflected. These effects all reduce the quality of the plateaux. The potential in the channel looks like a saddle, dropping at the ends but rising at the sides, and if these two dependencies are approximated as parabolaes, the ratio of their curvatures turns out to determine the quality of the plateaux, as subband spacing competes with end-to-end tunneling (Büttiker, 1990). For a precise treatment of the two-terminal conductance across a system such as the split-gate device shown in Fig. 2, we refer the reader to (Stone and Szafer, 1988), which introduces the Landauer and Landauer-Büttiker formalisms in great detail. These enable calculation of the conductances of two-terminal and multiterminal systems, respectively.

Fundamentally, the importance of observing quantized conductance along 1D channels was that it established the idea that quantization could be achieved solely by the application of an electric field and not just a magnetic field, the latter having already been established through the quantum Hall effect. Following the discovery of the fractional quantum Hall effect, similar attempts were also made at achieving fractional conductance in the absence of a magnetic field, though experimental evidence has remained lacking.

Interaction effects in 1D

The remarkable quantized conductance steps described above can be explained without considering interactions between the vast numbers of electrons carrying the current. In 2D and 3D, Landau Fermi-liquid theory shows that such interactions can be hidden by considering low-energy excitations of the system of interacting particles away from equilibrium, which behave like particles (“quasiparticles”) with energies just above or below the Fermi energy. However, in a truly 1D system (infinitely long, with just one subband), such excitations are unstable and, instead, the system can be treated as having bosonic excitations (like sound waves) in the Tomonaga-Luttinger model (see below).

Experimentalists therefore searched for many-body effects in their 1D wires long after the discovery of quantized conductance, with specific focus being allocated to the possible emergence of fractional charge and conductance in low dimensions. In 1996, Thomas and collaborators reported on the observation of an anomalous new plateau-like feature around $0.7 (2e^2/h)$, see Fig. 6, nowadays commonly known as the “0.7 structure” (Thomas et al., 1996). Interestingly, on application of an in-plane field, this feature was observed to move down to e^2/h , suggesting that the transmitted states were becoming fully spin-polarized, despite the absence of a magnetic field to define a polarization direction. Similar decrease of the plateau height was also observed upon increase of temperature. Proposed theoretical explanations for this phenomenon have included spontaneous spin polarization (Reilly, 2005) as initially suggested by Thomas et al., possible Wigner crystallization (Matveev, 2004; Güçlü et al., 2009), the Kondo effect (Meir et al., 2002; Rejec and Meir, 2006), ferromagnetic spin coupling (Aryanpour and Han, 2009) and, more recently and convincingly, a van Hove singularity in the local 1D density of states at either end of the pinched-off channel which enhances interactions and hence tunneling along the channel (Bauer et al., 2013).

As mentioned above, in 1D there should theoretically be a complete breakdown of the single-particle picture and Fermi-liquid theory. The Tomonaga-Luttinger liquid (TLL) model predicts, instead, a highly-correlated state of matter that forms when electrons are confined to a 1D geometry, where there are so few degrees of freedom that interactions cannot be hidden (effectively because electrons cannot get past each other along the wire). While originally proposed by Tomonaga and Luttinger in the 1950s and 60s (Tomonaga, 1950; Luttinger, 1963), the current version of the theory is credited to Haldane, who finalized it in 1981 (Haldane, 1981). Its key predictions include the emergence of new types of collective mode for spin and charge excitations (commonly dubbed spinons and holons, respectively), the appearance of power-law behavior at and around the Fermi points $\pm k_F$, and charge fractionalization. This theory is exact, but only applicable at low excitation energies, (i.e., close to the Fermi energy), as one of its key assumptions is that energy varies linearly with wavenumber k near E_F , whereas this dispersion relation is really parabolic and only resembles a straight line for a small range of energies around E_F .

Experimentally, work on TLLs has been carried out using a variety of systems, from transport measurements in carbon nanotubes (Bockrath et al., 1999; Ishii et al., 2003), edge states (Chang, 2003; Grayson et al., 1998) and quantum point contacts (Anthore

Fig. 6 The “0.7 structure.” (a) Evolution of a feature starting at $0.7(2e^2/h)$ to e^2/h when in the presence of a magnetic field B parallel to the wire. (b) Temperature dependence of the same feature shown in (a) for $B=0$. From Thomas KJ, Nicholls JT, et al. (1996) Possible spin polarization in a one-dimensional electron gas. *Physical Review Letters* 77: 135–138, reprinted with permission.

et al., 2018), to ARPES measurements in high- T_c superconductors (Kim et al., 1996) and organic compounds (Zwick et al., 1998; Pouget et al., 1976) and, more recently, time-resolved measurements in cold-atom chains (Vijayan et al., 2020). All these systems have, to different extents, validated the predictions of the TLL model. A different approach, however, considered tunneling measurements done in semiconductor quantum wires (Auslaender et al., 2005; Jompol et al., 2009).

Jompol et al. showed, by conducting a series of detailed energy- and momentum-resolved tunneling measurements between an array of 1D wires and a nearby 2DEG, that the spectral function of a 1D system is indeed double-peaked near the Fermi points (Jompol et al., 2009). This allowed for a clean observation of what is now known as spin-charge separation, that is, the separation of spin and charge degrees of freedom at low energy near the Fermi points, see Fig. 7. Power-law suppression of the tunneling near zero

Fig. 7 Spin-charge separation—theory and experiment. (a) Simulated dispersion of non-interacting electrons in 1D close to the Fermi point ($B^* = 3.40$ T). Here $B \propto$ momentum and $V_{dc} \propto$ energy. Note how all features track the non-interacting parabola (black full and dashed). (b) Measured dispersion. In addition to the parabola shown in (a), an additional feature not predicted by the non-interacting model (red dashed) is also observed. This is seen to branch away from the spin parabola (black dash) at the Fermi point, consistent with the behavior predicted by the Luttinger model for the charge mode. Note that the Fermi energy in this system is ~ 2.5 meV. From Jompol Y, et al. (2009) Probing spin-charge separation in a Tomonaga-Luttinger liquid. *Science* 325: 597–601, reprinted with permission.

(c) Same as in (b) but now for $G(|V_{dc}|)$ at constant $T < 100$ mK. (d) Curves in (a) collapsed on to one curve by plotting vs $V'_{dc} = \sqrt{|V_{dc}|^2 + (3k_B T/e)^2 + V_{ac}^2}$ where V_{ac} is the AC measurement voltage. From Jompol Y, et al. (2009) Probing spin-charge separation in a Tomonaga-Luttinger liquid. *Science* 325: 597–601, reprinted with permission.

source-drain bias V_{dc} , known as the zero-bias anomaly, was also observed in the same system at low temperatures T , see Fig. 8. Note that neither of these results can be explained by the Fermi-liquid model, but they are predicted by the TLL model.

Given the constraints of the theory from its initial assumptions of linearity, attempts at extending it to the nonlinear regime have also been carried out theoretically, particularly by Imambekov, Glazman and Schmidt, initially ignoring spin (Imambekov and Glazman, 2009) and then including it (Schmidt et al., 2010a). Here, by taking into account explicitly the curvature of the dispersion, momentum-dependent power laws and finite lifetime for the plasmonic excitations (i.e., when spinons and holons cannot be separately resolved) were also predicted, both recently observed experimentally (Jin et al., 2019; Wang et al., 2020).

The question of what happens to spin-charge separation at high energies and, therefore, away from the linear regime remained, however, unanswered: theoretically, the TLL model is no longer valid, with the general understanding being that all collective modes would eventually become unstable far from the Fermi points, $\pm k_F$. Experimentally, on the other hand, they had long been observed to remain stable up to, at least, the Fermi energy, already significantly away from $\pm k_F$, see Fig. 7B. Recent work has proposed a novel phenomenological picture to explain this apparent contradiction, by invoking the emergence of two Fermi seas, rather than the usual single Fermi sea (Vianez et al., 2022).

By measuring the spectra of a 1D system in a similar fashion to the work done by Jompol et al., but now also carefully accounting for the “parasitic” background signal from the 2D leads, it was observed that the measured resonances gave rise to two parabolic dispersions, or “Fermi seas,” see Fig. 9. These were seen to evolve separately from the already observed spin-charge feature at low energy, prompting the conclusion that the collective charge mode was still remaining stable even when at energies far above or below the Fermi points, as predicted theoretically by (Schmidt et al., 2010b; Tsypliyatsev, 2022). This work also observed a number of emerging higher-order 1D “replica” modes, in addition to the main 1D mode, as expected from the microscopic nonlinear model first developed by Tsypliyatsev (Tsypliyatsev et al., 2015, 2016; Moreno et al., 2016), see Fig. 10. Ongoing efforts, both theoretical and experimental, are currently attempting to explore these nonlinear signatures further.

Fig. 9 Two Fermi seas for spin and charge. (a) Proposed many-body spectra for an interacting 1D systems. Here, gray marks the many-body continuum while white the forbidden regions. (b) Map of the tunneling conductance differential dG/dV_{DC} as a function of DC bias V_{DC} ($\propto$ energy) and in-plane magnetic field B ($\propto$ momentum), showing the dispersion of a 1D system when in the single-subband regime. Superimposed curves mark all possible single-electron tunneling processes in this system, with the resonant dispersions of the spin and charge modes being marked by green and magenta dashed lines, respectively. Inset: dG/dB differential around the $+k_F$ point showing the spin-charge separation feature from which the velocities v^s and v^c can be extracted. From Vianez PMT, et al. (2022) Observing separate spin and charge Fermi seas in a strongly correlated one-dimensional conductor. *Science Advances* 8: eabm2781, *reprinted with permission*.

Fig. 10 Higher-order 1D “replica” modes. In addition to the main 1D dispersion, higher-order 1D features are also expected (dashed lines in Fig. 9a). Here, the first and second columns show, respectively, the dG/dV_{DC} and d^2G/dV_{DC}^2 tunneling conductance differentials, while the third column shows line cuts of the raw data, just above the $+k_F$ point. As can be seen, a feature compatible with a 1D “replica” mode is observed experimentally to become more pronounced as the length of the system L is decreased, as predicted by Tsyplatyev et al. (Tsyplatyev et al., 2015, 2016). From Vianez PMT, et al. (2022) Observing separate spin and charge Fermi seas in a strongly correlated one-dimensional conductor. *Science Advances* 8: eabm2781, *reprinted with permission*.

Conclusion

While the experimental study of transport and interaction effects in one-dimensional semiconducting devices first started in 1988 with the simultaneous discovery of conductance quantization by two different groups (van Wees et al., 1988; Wharam et al., 1988), the field is still producing new and unexpected results, from fractional quantization (Thomas et al., 1996; Bauer et al., 2013), to spin-charge separation (Auslaender et al., 2005; Jompol et al., 2009), possible helical order in the nuclear spins (Scheller et al., 2014; Braunecker et al., 2009) and, more recently, nonlinear effects (Wang et al., 2020; Jin et al., 2019; Vianez et al., 2022). The influence of spin-orbit interaction (SOI) on transport in 1D has been studied carefully experimentally (for holes in GaAs) and theoretically very recently (Hudson et al., 2021), and SOI has been shown to separate spins leaving a 1D channel (Lo et al., 2017) and to allow control of the Kondo effect (Smith et al., 2022). Outside the solid state, recent technological improvements have also, very recently, allowed for perfect, disorder-free 1D systems to be created using a lattice of optical traps rather than a semiconductor crystal (Vijayan et al., 2020), showing good promise for future results not just in 1D but perhaps, in higher dimensions.

Abstract

This chapter is an introduction to the physics of one-dimensional quantum interacting systems. It presents the basic concepts and properties of such systems as well as their differences compared to higher dimensional ones. It introduces the concept of the Tomonaga–Luttinger liquid, the cornerstone of our description of 1D quantum systems. It discusses the main theoretical methods to attack such problems, the main experimental realizations and the main challenges in the field, both current and future.

Key points

- Main ingredients in a one-dimensional quantum system
- Peculiar physics consequences of the collective character of a 1D system
- Presentation of the concept of Tomonaga–Luttinger liquid
- Main experimental realizations of 1D quantum systems
- Successes and current and future directions.

Introduction

Correlated quantum systems are one of the main outstanding problems in modern quantum physics, with far-reaching consequences ranging from solid state physics and material science to information theory. In such systems a large number of particles (anything from a few hundred in cold atomic gases to 10^{23} in solids) interact together. In addition, due to the indiscernibility of the particles (whether bosons or fermions), the wavefunction has to be totally symmetrized or antisymmetrized, leading to very complicated entanglement properties and making this problem extremely challenging to solve on classical computers. Of course the complexity of the problem is also the warrant of the richness of the physics it can lead to and such systems have led to remarkable physical phenomena, such as superconductivity or quantized Hall response, to name a few.

One could naively imagine that for such problems the spatial dimension is only marginally relevant. This is indeed the case for many properties when the dimension is two or above (there are notable exceptions, in particular for dimension two). However, one dimension stands apart. Indeed, in such a case particles cannot avoid each other, contrarily to what can happen in larger dimensions, and thus even an *infinitesimal* interaction can drastically modify the physical properties compared to the noninteracting case. In addition, edges in one dimension are reduced to two points, making it easier to classify solutions by the behavior at the edge of the system. Topological properties are thus the rule rather than the exception. Finally, the lower the dimension the stronger the thermal and quantum fluctuations, rendering typical “mean field” methods useless; one finds oneself in a realm of physics where not only the physics is radically different, but the set of methods that one must use to solve is also unusual.

Such one-dimensional quantum systems were once considered pure theoretical exercises or “toy models” that one attacks before trying the real high-dimensional challenge. Fortunately, this is not the case anymore. On the pure theory side, they have shown remarkable physics properties that are studied in their own right. They have also led to the development of analytical and numerical techniques that have changed the way we are now looking at correlated systems. Even more importantly, the number of

experimental realizations of such systems has literally exploded in the 21st century, as well as the ways to probe such systems, in both equilibrium and out of equilibrium situations.

The goal of this chapter is thus to give a brief digest of this unusual one-dimensional quantum physics and an idea of the methods used to tackle it. Because of the structure of this chapter, most of the references will not be in the text but can be found in the various textbooks and reviews that are listed in the “Further reading” section. Some exceptional references are listed in the text as well.

Fundamental concepts for 1D systems

Let us first give a very brief digest of some of the essential properties of one-dimensional systems.

1D or not 1D

One-dimensional systems can be realized, in our three-dimensional world, essentially with three different incarnations as illustrated in Fig. 1.

The most common one comes from materials that have a three-dimensional structure but for which there is a large anisotropy in the energy scales for kinetic energies (fermions or bosons) or magnetic exchanges (localized spin systems). Let us generically denote $t_{\parallel}$ the energy along the “chain” direction and $t_{\perp}$ the one in the transverse direction. In that case, if either the energy at which the system is probed or more simply the temperature T satisfies $t_{\perp} \ll T \ll t_{\parallel}$, the system is quantum mechanically coherent along the “chain” direction but motion along the perpendicular direction is essentially incoherent, or does not have time to occur before the system is probed. In that case, one can consider that the system can be described by a one-dimensional Hamiltonian and ignore the couplings in the transverse direction. This is the most common case and is realized, for example, in spin chains and ladders,

Fig. 1 Various types of one-dimensional structures. Top: a system with many chains (here represented in two dimensions, but in general three dimensional) but with a very strong anisotropy in the kinetic energy, or as shown here, tight binding hoppings. When the temperature is much larger than the transverse hopping $T \gg t_{\perp}$ the system is incoherent in the transverse direction but perfectly coherent along the chains if $T \ll t_{\parallel}$. In that case the system is effectively behaving as decoupled 1D chains. When the temperature is lowered the system undergoes a dimensional crossover toward a two- (or three-) dimensional situation. This applies to three-dimensional crystals such as organic conductors and superconductors, or quantum spin chains and ladders and some cold atomic gas realizations. Middle: a structure confined enough in two directions with size small enough compared to the quantization of energy levels in the transverse direction would lead to large energy changes, much larger than the temperature or the interaction energy. In that case the transverse part of the wavefunction is blocked in the fundamental of the system $\phi_0(x)$ and these quantum numbers cannot change. The only quantum number that can change is the one along the z direction. Thus the system behaves as a perfect one-dimensional system even if its physical dimensions are not zero in the transverse directions. This system will stop being one dimensional when the temperature or the interaction becomes large enough to be able to excite the transverse degrees of freedom. In that case several transverse quantum numbers are involved and the system becomes somewhat similar to the one on the top but with a *finite* number of chains (so-called ladders). Bottom: In some systems such as fractional quantum Hall effect or topological insulators, the bulk of the system is gapped but the edges are gapless. In that case we have a special case of one-dimensional system that is chiral since the particles moving on the right direction are physically separated from the particles moving on the left.

organic conductors and superconductors, and cold atomic systems. It is important to note that in such systems when the temperature is lowered below $t_{\perp}$ the system will not be one-dimensional any more. This paves the way to studying the very important dimensional crossover that can occur in these systems and that we will discuss more in the Section “Key issues and future directions.”

The second possibility is to confine the two transverse dimensions to small enough distances such that the quantization of transverse quantum numbers ensures large enough energy differences. Let us illustrate it by a system in which the directions x and y would be put in a harmonic confinement potential while the direction z is essentially a continuum. In that case, the wavefunction of the system is of the form

$$\psi(x, y, z) = \phi_n(x)\phi_m(y)e^{ikz} \quad (1)$$

where ϕ_n are the eigenstates of the harmonic oscillator with quantum number n and thus of energy $E_n = \hbar\omega_0(n + 1/2)$. Changing the transverse quantum numbers from, for example, $n = 0$ to $n = 1$ thus costs a finite amount of energy $\hbar\omega_0$. Similar results would be obtained by other confining potentials such as a box. Thus, provided that temperature and interactions are lower than this discrete difference in energy, the transverse quantum numbers are frozen and the system behaves quantum mechanically as a purely one-dimensional system. This realization of one-dimensional systems is directly relevant for cold atomic systems, quantum wires, and nanotubes. Note that, contrarily to the previous situation, there is not here a dimensional crossover, but if the temperature or interactions become too large it is necessary to take into account other transverse quantum numbers, as shown in Fig. 1. This is thus similar to a multiorbital or finite number of one-dimensional structures coupled together. This situation, known under the generic name of “ladders,” is still one-dimensional asymptotically but in general with properties quite different than those of a single chain.

Finally, the last realization occurs when one has a system for which the bulk is gapped but edge states that are gapless can exist. This is the case, for example, in systems with fractional Hall effect or topological insulators. In that case the edge states are confined and one is for each edge state in a similar situation to the confined realization described earlier. The main difference is that now the system is chiral in the sense that right-going particles and left-going particles are separated at the edge, contrarily to the case of a normal one-dimensional structure. This has important consequences when interactions are put into play, since a right mover cannot be converted to a left mover (so called backscattering), contrary to the case of a normal one-dimensional structure.

Collective excitations and 1D physics

One-dimensional systems possess a set of characteristic features that set them apart from their higher dimensional counterparts, whether they are spins, bosons, or fermions. It is of course out of the question to be exhaustive here but we will brush the main concepts. We will see first the properties and then briefly discuss the methods that can be employed to obtain them.

Many important properties of one-dimensional systems have their origin in the fact that because of the 1D character particles cannot avoid each other. This means that it is impossible to separate the properties and even the statistics of the system from the interactions. It is relatively easy in 1D to pass from fermions to bosons to spins. Indeed, an infinite repulsion between bosons produces identical effects to the Pauli principle for fermions. A corollary of this tells us that individual particle excitations, such as those existing for free particles or those that make up the essence of Landau’s Fermi liquid, the paradigmatic solution of interacting high-dimensional fermions, will not exist in general in one dimension. Any excitation will rapidly transform into *collective* excitations. A second defining property is the fact that in low dimension it is extremely difficult to break symmetries due to fluctuations. Even at $T = 0$ a continuous symmetry cannot be broken and only discrete ones can lead to true order. Thus a typical one-dimensional system has usually only quasilong range order even at $T = 0$.

Quite remarkably these properties have given rise to a unifying concept that plays a similar role to that the Fermi liquid has played for high dimensional fermionic systems, or Bogoliubov theory for bosonic and spin systems. This is known as the concept of Tomonaga–Luttinger liquid (TLL), discovered by Haldane (1980, 1981a, b), which describes the properties of many massless one-dimensional systems and serves as a stepping stone to study either more complicated situations (coupled chains, several degrees of freedom, more complicated interactions, etc.) as we will discuss in the Section “Complications.” The TLL is characterized by a low-energy Hamiltonian describing excitations, that are collective excitations such as sound waves (representing density fluctuations of the system). It is fully characterized by two parameters, the velocity u of the excitations and a dimensionless parameter K . The spectrum of excitations is thus linear $\omega \sim uk$. The correlation functions are characterized by harmonics that vary in space with a wavevector multiple of $2\pi\rho_0$ where ρ_0 is the average density of the system. For fermions it is easy to see that this corresponds to $2k_F$ where k_F is the Fermi wavevector. The corresponding amplitudes of the various harmonics decay as a powerlaw of space x or imaginary time τ with exponents that are only functions of the dimensionless parameter K . Let us give an example with a one-dimensional system of interacting bosons. The single particle Green’s function and the density–density correlations behave respectively as

$$\begin{aligned} \langle \psi_B(x) \psi_B^\dagger(0) \rangle &= A \left(\frac{\alpha}{x} \right)^{\frac{1}{2K}} + \dots \\ \langle \delta\rho(x) \delta\rho(0) \rangle &= \frac{-K}{2\pi^2 x^2} + B \cos(2\pi\rho_0 x) \left(\frac{\alpha}{x} \right)^{2K} + \dots \end{aligned} \quad (2)$$

and similar decays in imaginary time. The TLL is thus a conformally invariant theory with a central charge $c = 1$. This easily allows computing of finite temperature properties. As can be expected from general grounds, the finite temperature that introduces a periodicity of period β the inverse temperature in the imaginary time direction transforms the system into essentially a classical one-dimensional system with exponentially decreasing correlation functions. The A and B are nonuniversal amplitudes that depend on the precise microscopic model and the ultraviolet cutoff α (akin to a lattice spacing and regularizing the regime that follows, for which the field theory representation is not valid any more). We will discuss in the Section “Methods” how to compute these amplitudes as well as the TLL parameters u and K .

As a consequence of having one or several correlations that decay as powerlaws, the corresponding susceptibilities can easily diverge (depending on the value of K) and the TLL is thus a system that, like a critical system, is poised at the border of ordering. It will thus be very sensitive to external perturbations such as periodic potentials or the existence of a lattice (leading to Mott transitions), disorder (leading to localized phases, with or without interactions), or coupling of several chains or degrees of freedom together.

Of course, one is not limited to a single degree of freedom and the preceding easily generalizes to several components coming, for example, from spin. This is, for example, the case for the celebrated Hubbard model of fermions with spin-1/2 and a contact interaction. This brings us to another important characteristic of one-dimensional systems: the fractionalization of excitations. Usually there is a minimal excitation that can be done in a system and all more complicated processes are multiples of this elementary process. For example, in high dimensional spin systems the minimum variation of spin in a spin 1/2 system consists of flipping one single spin with a modification of the z component of the spin by $\Delta S^z = 1$. This excitation, which is commonly referred to as a magnon, is the building brick of higher excitations. In a similar way, for a fermionic system the least one can do is to remove one electron, which removes both a charge 1 and a spin 1/2. This is the basic quantum numbers of a Landau quasiparticle. In one dimension, because the individual excitations are transformed into collective ones, they usually *decompose* into (i) nonlocal; (ii) more elementary excitations. One simple example, shown in Fig. 2, is the decomposition of the magnon (local “elementary” excitation) into two real elementary excitations, the “spinons” carrying each only a spin 1/2. These excitations are nonlocal, which is why a local probe must create these excitations in pairs. On the other hand, in the one-dimensional world nothing prevents them separating (deconfining). This leads to severe consequences such as continua of energy since the energy of an excitation with a given momentum can be spread between the two spinons in an arbitrary way. Last but not least, since the boundary in one dimension is essentially two points ($x \rightarrow -\infty$ and $x \rightarrow \infty$), it is easy to classify solutions based on the value of fields at infinity and thus to have a topological index. Thus in 1D, topological excitations are the rule rather than the exception.

This fractionalization of excitations generalizes to more complicated models such as fermions with spins. In that case the Hilbert space asymptotically separates into a sector that carries charge and no spin (“holon” excitations) and a sector that carries spin but no charge (“spinon” excitations). These two excitations deconfine, showing that individual (Landau) quasiparticles do not exist in one dimension. This phenomenon, known as spin-charge separation (see Fig. 2), has consequences in particular for the photoemission spectrum of 1D systems.

Fig. 2 Top: The most elementary excitation in a spin 1/2 chain consists of flipping a single spin. The smallest change of the spin quantum number is thus $\Delta S_z = 1$. In dimension greater than one, this is an elementary excitation (known as a magnon), with a well defined relation between the momentum of the excitation and its energy (and a finite lifetime). In real space this corresponds to the block of down spins indicated on the top figure. Middle: in one dimension this excitation can decompose in two deconfined *collective* excitations: the spinons. Each spinon carries a $\Delta S_z = 1/2$. This thus corresponds to a fractionalization of the excitations. Note that the spinon is not a local excitation since it consists both of two down spins but also of a string on the left or on the right of the two down spins of overturned spins (symbolized by the *box* in the middle figure). In a strict one-dimensional situation, this string does not cost energy and the two spinons are deconfined. In the presence of adjacent chains (thus in a higher dimensional system) the string costs an energy growing linearly with the length of the string and thus confines the spinons, leading back to the magnon as an elementary excitation. Bottom: When charge (symbolized by the *ball*) and spins (symbolized by the *arrow*) degrees of freedom are present such as in the fermionic Hubbard model, a similar fractionalization of excitations takes place. Removing a particle (thus both a charge and a spin up) leads to two deconfined excitations. The holon is missing a charge but has an otherwise undistorted spin background. The spinon has no charge missing but has a spin up missing (two close spin down).

Methods

Before going too deep into the properties of more complex 1D systems, it is important to say a word about methods. Indeed, as mentioned earlier the special nature of 1D system, invalidates many of the methods commonly used in higher dimensions such as naive mean-field theory. Methods specific to one dimension had to be developed and met with considerable success. I will examine some of them here, confining myself to the simple situations. More sophisticated cases will be mentioned together with the novel problems they refer to in the Section “Key issues and future directions.”

The first type of method that comes to mind when discussing 1D systems is the Bethe ansatz (BA). Indeed, in one dimension and for very specific models it is possible to write the wavefunction of the fundamental exactly and to understand the excitations. This method, pioneered by [Bethe \(1931\)](#), has allowed considerable progress to be made. In particular, thanks to the works of E. Lieb, systems such as interacting bosons ([Lieb and Liniger, 1963](#)) and interacting fermions on a lattice (Hubbard model) ([Lieb and Wu, 1968](#)) could be explored in depth. The method has, however, the drawback of being limited to integrable models, and very often whether the model is integrable or not is the only information that one can extract. It is also difficult to ascertain how generic is the integrable model. Despite this limitation, this method has been extremely useful, leading to a good understanding of the excitations and the thermodynamics of several 1D models. During the last 20 years or so it has seen extremely strong progress, and now even physical correlation functions of important models such as the Lieb-Liniger model or the XXZ spin chain can be computed. I will also come back to this method when dealing with the more complicated case of out of equilibrium physics in the Section “Key issues and future directions.” The method allows one to deal both with models in the continuum (Lieb-Liniger model of bosons) or on lattices (Fermi Hubbard model), and is of course able to deal with both finite size systems and the thermodynamic limit of an infinite size system.

The second class of method includes the numerical ones. One dimension is well adapted from the start to such methods since boundaries are quite small (on 100 sites the boundary is only 2 sites, while in two dimensions a 10×10 equivalent system would have a boundary of 36 sites). This makes methods such as exact diagonalization that give an essentially exact numerical answer much more efficient in one dimension (typically able to treat about 40 sites for spin $1/2$ systems). Of course, all the standard numerical methods (e.g., quantum Monte-Carlo) can be used in 1D with essentially the same limitations as in higher dimensions. In addition, 1D has led to the development of specific methods that have played a major role. This is in particular the case of the so-called Density Matrix Renormalization Group (DMRG) method, invented by [White \(1993\)](#). This method is essentially a highly intelligent variational approach where an optimal wave function approaches the ground state in an *unbiased* way. This method has given access to static correlation functions with an unprecedented level of accuracy. It was then recast in the more general framework of matrix product states, which allowed extending it more easily to dynamical correlations and time-dependent Hamiltonians than was possible in the past. As a result, the application of this method has literally exploded in the last 20 years or so to make it an indispensable tool for the properties of 1D systems. As a result, many properties (both static and dynamics) of 1D systems (even made by a limited number of 1D legs) can be computed. Importantly, at variance with methods such as for example, quantum Monte Carlo this method does not suffer from growing errors (the so-called sign problems) and can be used generally for 1D systems. It is limited by the growth of entanglement, and thus although it works well for pure 1D systems its computational cost becomes rapidly prohibitive for coupled chains. To give some numbers, the equilibrium properties of a 1D system of typically 100 sites can be computed down to energy resolutions of $J/20$, where J is the typical energy scale of the system. This is often better than the resolution of the probe itself and, for example, structure factors of spin chains and ladders could be computed brute force with this method. It is particularly well adapted to systems on lattices, and of course is essentially exact at all energies for a given microscopic Hamiltonian.

Last but not least, 1D systems have been studied via field theory methods. The best known is called bosonization and consists of rewriting the single particle excitations of the system in terms of the collective excitations (sound waves). Given the peculiar nature of 1D, this “change of variables” is possible. The denomination is historical since it was first applied to fermionic systems for which the spectrum can be linearized near the Fermi points, allowing an analysis that becomes semicontrolled in the curvature of the dispersion relation. But this is a generic procedure, as beautifully shown by [Haldane \(1981a\)](#), so the important part is not so much the change of statistics as the “collectivization” of the degrees of freedom. As with any field theory, the applicability is limited to low-energy properties (long distance compared to, e.g., a lattice spacing and long times compared to an elementary time, which is the inverse of the typical energy scale). Field theory has thus the drawback of being limited to low energies and to depend on a certain number of phenomenological couplings (such as, e.g., a high energy cutoff). It has on the other hand the advantage of being quite generic and of immediately incorporating in a unified field description many different microscopic models. It is thus particularly well adapted to condensed matter problems for which we usually know poorly the real microscopic Hamiltonian (which usually contains a complicated energy-dependent screened Coulomb interaction) and for which the typical energy scales, bandwidth, or spin exchange constants are usually in the thousands of Kelvins. The phenomenological parameters are thus as good as the “original” parameters of the Hamiltonian. The field theory allows for a very simple description of the system and because it uses the right collective basis the Hamiltonian is already in a much more diagonal form than when written in terms of single particles. Thus the bosonization methods have allowed the cracking of extremely simply models or those as complicated as the Lieb-Liniger model or the fermionic Hubbard model. Much more importantly, since it is a dictionary it can be used as a stepping stone to tackle much more complicated problems (many degrees of freedom, several chains, etc.).

These three classes of methods have thus played an important role in our understanding of 1D systems. But each one of them has its own limitations, as already mentioned. BA is restricted to specific models and it is difficult to extract nonthermodynamics

Fig. 3 Symbiosis between the three main methods used in one-dimensional systems. *Green* shows the advantages of the method, *red* the main drawbacks, and *blue* some of the connections between the methods. The possibility of having these three methods working in symbiosis and used in the range of energies or parameters for which they are the most efficient has allowed solutions for most of the 1D simple problems.

quantities. Numerics is good for short times and distances and becomes inefficient at too large times and distances. Field theory rests on certain phenomenological parameters and is only efficient at large distances and times. What was remarkable in the last 20 years is that the 1D community has learned to use these methods in symbiosis and thus practically obtain a complete and semixact description of simple 1D physics, as shown in Fig. 3. Numerics is used to obtain *directly* the correlation functions at intermediate time and distance for a given microscopic model. As mentioned, this already allows going quite far in distance and time. Moreover, using a trick developed by Haldane (1980), one can also use the numerics to obtain essentially *exactly* the phenomenological parameters, such as the TLL parameters and the amplitudes that need to be injected in the field theory. These parameters can also be extracted from the BA when available. This allows an essentially *quantitatively* exact field theory that can then be used to get the large distance and large time behavior of the correlation functions, in regimes that the numerics could simply not reach. This method has been used with great success and has allowed us to obtain essentially exact descriptions of various 1D systems, and is has put us in a unique position to use these tools to tackle more complicated situations.

Complications

Before discussing to the most active problems in the Section “Key issues and future directions”, let us first examine three especially interesting complications of purely 1D systems that have been particularly fruitful and are the backbone of some of the current studies in the field.

Mott transition

As indicated earlier, 1D systems are exceptionally sensitive to perturbations, given the quasilong range order existing in several correlations. This is in particular the case for the density, and thus the effect of a lattice can be particularly important. The lattice can be either put as a weak perturbation on top of a continuum model $\int dx \cos(Qx) \rho(x)$ or can exist from the start if the model is defined on a lattice, such as, for example, Hubbard models. In both cases it is well known that the combination of lattice and interactions can lead to new insulating phases. This is the well-known Mott transition for which, at commensurate filling, the interaction can turn a metal or a superfluid into an insulator. The lattice breaks the continuous translational symmetry into a discrete one, which can be broken even in 1D at zero temperature. As a result, Mott phases exist. There are too many to be mentioned here, so some of them are pictorially shown in Fig. 4. An important difference compared to higher dimensions is that in 1D the Mott phase can be reached even for an *arbitrarily weak* lattice, provided the system is interacting enough. This has been beautifully evidenced by experiments in cold atomic gases with bosons at one particle per site. On the field theory side, the Mott transition at constant density (Mott-U transition) when the interaction is varied is described by an effective sine-Gordon theory. It is thus in the universality class

Fig. 4 Top: Particles in a continuum system to which a small periodic lattice has been added. In 1D if the repulsion between the particles is large enough, even a very small lattice much smaller than the kinetic energy of the particles can lead to a Mott insulator phase with one particle at each lattice minimum. Bottom: a tight binding model where the particles jump from site to site. Here we get only a discrete translational symmetry, and the repulsion between the particles can again lead to a Mott insulating phase, shown here with exactly one particle per site.

of the celebrated Berezinskii–Kosterlitz–Thouless (BKT) transition and indeed a mapping exists between the 1D quantum model and the two-dimensional classical XY model that is the seat of the BKT transition. This also illustrates the importance of topological excitations, as mentioned earlier. Measurements of the quantum phase transition between the Mott and the superfluid phase of bosons is in effect one of the very precise tests of the universal character of the BKT transition. The Mott transition can also occur for other commensurate fillings depending on the statistics and is always described by a modified sine-Gordon Hamiltonian. Quite interestingly, one can also study the transition when the density is varied (Mott- δ transition). The nature of the transition is very different, being now mappable on the so-called commensurate–incommensurate or Pokrovsky–Talapov transition. This transition, which corresponds to free fermions close to an empty band, has different critical exponents (for example, $z = 2$ for the dynamical exponent relating energy to momentum, contrarily to $z = 1$ for the Mott-U transition) and can also be studied and measured in great details, for example in quantum spin systems. The ability to describe such transitions is one of the clear successes of the field theory description (bosonization) of 1D systems.

Effect of disorder or quasiperiodic potentials

Another very important class of problems, somewhat connected to the case of the Mott transition, is the effect of disorder on 1D systems. Indeed, it has been known since the works of Anderson that even an infinitesimal disorder can transform a 1D interacting system from a system made of delocalized wave functions to a system where all the eigenstates are exponentially localized. This is the celebrated Anderson localization. A crucial question is, of course, how the interactions can affect this behavior, leading to the question of the localization or not of interacting particles (LIPs). For one-dimensional systems this problem can be studied in a similar way to the Mott transition by adding a term $\int dx V(x) \rho(x)$ to the Hamiltonian, where $V(x)$ is a suitable random potential. Of course, many other terms are possible, such as random hopping or quasiperiodic potentials, which have been studied both theoretically and experimentally. Field theory and numerical descriptions allow this problem to be tackled even in the case of interacting fermions and bosons and to show that the localization resists in the presence of interactions and to compute the effect of interactions on the various properties of the system. For example, for one-dimensional interacting bosons a quantum phase transition exists between a superfluid phase for moderately repulsive bosons to a Bose glass phase that is localized when the repulsion between bosons exceeds a certain threshold. This phase was also analyzed for quasiperiodic potentials and was realized experimentally in cold atomic systems. Similar results were obtained both for localized fermions and quantum spins.

One interesting question is how interactions affect the transport properties of the localized phase. This question is interesting both for the frequency dependence of the conductivity and for its temperature dependence. The frequency dependence can be computed exactly for the noninteracting system and by using the field theory and numerical approaches for the interacting one, showing a deep change of the properties both in terms of the localization length and the frequency dependence as a function of the interactions. The temperature effects are more subtle and have been the subject of intensive studies recently. In the presence of an external bath allowing exchanges of energy between the system and the bath (such as phonons), the answer was provided for the noninteracting system by Mott and is known as Mott’s variable range hopping. Extensions to the case of Coulomb interaction in high dimensions were given by Efros and Schlovskii. The field theory analysis of the one-dimensional interacting system confirmed this expression and computed fully the conductivity, which becomes a function of the TLL parameters. One important question was, however, what happens in the absence of an external bath, and it was proposed that the system would stay perfectly insulating even at finite temperature. This is the so-called many-body localization (MBL) problem. Extensions of this problem allow one to ask whether even at infinite temperature the system would have a transition from a localized phase where the system is not ergodic to a phase where ergodicity is restored. Experiments in cold atoms allowed probing of these questions.

Coupled chains

Last but not least, one important extension of 1D systems consists of coupling 1D units. This is a very natural thing to study in view of how most 1D realistic systems are constituted. In addition to looking at the coupling of an infinite number of chains as mentioned in the Section “Fundamental concepts for 1D systems” it is interesting to look at a small coupling of 1D units (ladders). This is relevant both for a certain number of experimental systems, and also from a purely theoretical point of view. Indeed, as was

shown spectacularly by Haldane by looking at the dependence on the size of the spin S of the properties of a spin S chain, the properties are not smoothly evolving. There has thus been considerable activity to determine the properties of coupled chains both for a finite number of chains and for the infinite number of chains.

The question of a finite number of chains (so called ladder physics) has led to numerous studies. For spin systems this problem is deeply linked to the Haldane problem and a finite number of chains shows the same nonmonotonous dependence (two leg ladders have gapped excitations, while three legs have dominant antiferromagnetic correlations). This study is directly relevant for a certain number of experiments in quantum spin systems and such systems have even been used with success as quantum simulators. In a similar way, coupled bosonic ladders have been realized in cold atomic gases or in Josephson junction systems. A set of interesting questions comes from the competition between an insulating phase provoked by, for example, a Mott potential and the effect of interchain hopping that promotes superfluidity. Another different set of questions occurs when such ladders are subjected to an external magnetic flux. Indeed, the system becomes then a 1D variant of a superconducting film and the question of how currents at the edge and/or vortices can be observed is a nontrivial one that has been the subject of intense studies, given the realization of such systems in cold atomic gases. Fermionic ladders are the most surprising. The hopping of fermions, contrarily to the hopping of bosons or spin exchange, has no classical limit and thus cannot be treated by conventional mean-field theories. The treatment of this coupling is thus quite complicated and has succeeded thanks to the progress both in the field theories and numerics. The answers are quite surprising and two leg fermionic ladders have exhibited d -wave superconductivity stemming from *repulsive* local interactions. This remarkable result, which gives us one of the very few controlled paths to exotic superconductivity, is intensively studied both theoretically and more recently in cold atom experiments.

The other limit is that of coupling from the start an infinite number of chains and trying to address the question of the dimensional crossover between the 1D behavior with all the exotic excitations and the more conventional high dimensional one (in, e.g., three dimensions). For spin and bosons, a mean field treatment of the interchain coupling is usually possible in the absence of frustration, between the chains, and leads to conventional order with deeply modified critical temperatures and even order parameters due to the 1D nature of the elementary brick in the system. Such behavior could be quantitatively tested in quantum spin systems. For example, the confinement of spinons due to the presence of more than a 1D chain has been successfully observed, as well as the ordering of quantum ladder systems. Competition between 1D phases such as Mott and those provoked by the increased delocalization coming from the interchain coupling is also a deep class of problems. Although the mean-field description for spin and bosonic systems has been deeply successful in the absence of frustration the fact that we know now very well the behavior of the elementary 1D units also shows us its limitations. When frustration is present, the problem is essentially unsolved. This is also the case for fermions for which the question of the dimensional crossover between 1D and, for example, 3D is essentially open. The question of coupled chains is thus clearly one of the main challenges of 1D physics.

Key issues and future directions

The previous sections presented the success in describing 1D physics. This section discusses the main open issues in the field or those on which active research is currently being done. It also describes the trends and future directions.

One clearly exploding direction is that of studying systems that are out of equilibrium, whether because of a quench, or simply because the system is put in either a periodic (Floquet) perturbation or simply between reservoirs that impose a steady state (transport). This is clearly a novel situation for which most of the tools that were efficient in equilibrium have to be either adapted or invented anew. The field is far too broad and active to be fully described here, so I will simply give some examples. For quenches, efficient field theory descriptions had to be obtained both for massless and massive theories. But given that quenches occur on a very short timescale, the question of the possibility of a field theory description has to be raised. It is thus interesting to find more exact methods that could describe the system at all scales and at the same time take into account the nonequilibrium character. A promising development is provided by the so-called generalized hydrodynamics, a method merging the exact description of BA with the hydrodynamic nature of an out-of-equilibrium fluid. This method has already allowed the description of highly nontrivial experiments in cold atomic gases. Of course, as with any out-of-equilibrium situation the question of the asymptotic state and its thermalization, or not, is an important question that has been addressed both theoretically and experimentally. Finally, stimulated by experiments in cold atomic systems that could probe the transport through a one-dimensional structure attached through a variety of reservoirs with or without interactions, various properties of transport are currently being studied. This implies the development of new methods (for example, using the Keldysh formalism). Such situations are clearly an extremely active field at the moment.

A second direction for isolated chains involves the effects of disorder and related potentials (quasiperiodic, etc.). Although this question has been already intensively studied as discussed in the previous section, many open questions remain. This is in particular true for most of the transport quantities at finite temperature that still resist precise calculations. At infinite temperature, the very question of an MBL transition is still under debate and new methods are needed to attack this problem. Another important direction of research for isolated chains is the effect of boundaries and the presence of topological states at the edge. Most of the studies were done in the absence of interactions and of course in one dimension a very natural question comes from the very presence of interactions.

Finally, one of the most open and exciting directions is the way to go from the 1D world to the higher dimensional one. Given the reliability of field theory and numerical methods to obtain the 1D properties, it is a very natural route to explore how to couple

these structures together. This can lead to novel emerging properties, as was the case for fermionic ladders, but this is certainly a way to also attack the problem of the higher dimensional strongly correlated systems – a major remaining challenge in the field. It is of course also directly relevant to a large number of experimental realizations. Quite remarkably, the studies resting on mean-field descriptions have shown the great success of such approaches for bosons and spins, but also their very strong limitations. So, new methods are being tried, such as doing mean field on larger structures such as ladders or trying to incorporate fluctuations from the start beyond the mean-field description. For fermionic systems, the challenge is considerable, and going through the quasi-one-dimensional route might be a way to avoid some of the pitfalls posed by direct numerical attack on high dimensional fermion problems. It also leads to interesting phenomena, such as confinement of 1D excitations or, on the contrary, to deconfinement of certain insulating phases, given the extra kinetic energy introduced by the higher dimensional coupling. All these questions, going using the generic name of dimensional crossover, are extremely strong challenges that are currently pursued by a combination of analytical and numerical methods.

Conclusion

This chapter gives a brief tour of the remarkable physics of interacting one-dimensional quantum systems. The very presence of interactions and the impossibility of the particles avoiding each other in 1D leads to a remarkable set of properties: all the excitations become collective excitations and thus individual excitations as such, as we know in the higher dimensional world, do not exist any more, but decompose into these collective ones. This leads to a set of remarkable features, such as the fractionalization of excitations, as well as the very natural presence of topological properties. Most of the properties of simple 1D models, whether bosons, spins, or fermions, can be summed up into a simple effective model known as the TLL model, characterized by very few constants that control the decay of all the correlations of the system. Thus 1D systems constitute remarkable laboratories in which the quantum effects, with all their quirks and remarkable features, are at their maximum. They are poised at the verge of instability, which makes them very sensitive to perturbations such as disorder, lattices, or coupling between 1D units.

The 1D field, although explored extensively since the 1960s, has known incredible developments with the coming of the 21st century. Regarding methods, novel methods have appeared or been refined, whether on the analytical front or on the numerical one. More importantly, a way to make the complementary methods of exact solutions, numerics, and field theory work together has been found, allowing each method to be used in the energy range for which it is the most efficient, thus leading to an essentially exact description at all energies. At the same time, novel questions have emerged that have pushed these new methods to their limits, such as the study of edges and topological states, novel perturbations such as strong spin-orbit coupling, and out of equilibrium physics: quenches and their consequences on the physics of the systems and its thermalization or even transport properties in clean and disordered systems. Last but not least, the experimental realizations have exploded, both with the advent of cold atomic gases that have provided an incredible laboratory in which to study 1D physics, and also with novel realizations in condensed matter providing controlled realizations to study such physics.

The 1D physics is thus a very active field at the moment, with both solid solutions and also incredibly challenging problems. It is not only interesting to study by itself, but also provides a path to tackle the questions posed by higher dimensional systems.

Abstract

We introduce the Hubbard model as the paradigmatic model of materials with strongly correlated electrons. For integer filling the model undergoes a Mott–Hubbard transition as a function of the interaction strength from a metal to a Mott insulator with localized electrons. We briefly introduce Dynamical Mean-Field Theory, a powerful nonperturbative method which provides a comprehensive picture of the Mott transition. We comment about the role of multiorbital electronic structure and the Hund’s coupling.

Key points

- To introduce the Hubbard model and some historical aspects
- To introduce the Mott–Hubbard transition
- To present the Dynamical Mean-Field Theory and its scenario for the Mott transition
- To provide some information about multiorbital Hubbard models and the Hund’s coupling

Introduction

The Hubbard model plays a central role in modern condensed matter physics as the paradigmatic description of materials with narrow electronic bands, in which the screened Coulomb interaction leads to strong correlations between the electrons. It describes electrons hopping via quantum tunneling between the sites of a lattice and experiencing a local Coulomb repulsion which couples two electrons with opposite spin on the same lattice site, and it can be seen as a refined tight-binding model where a screened Coulomb interaction is added to the Hamiltonian describing electrons hopping between ions arranged in a periodic crystal.

The model has been first introduced independently in [Hubbard \(1963\)](#), [Kanamori \(1963\)](#), and [Gutzwiller \(1963\)](#) as a minimal description for narrow-band materials such as transition metals and transition metal oxides. The main motivation of these pioneering studies was the understanding of itinerant ferromagnetism, but the scope of the model turned out to be much wider. Transition metal oxides have indeed rich and complex phase diagrams, featuring different magnetic phases and metal–insulator transitions ([Imada et al., 1998](#)), as well as different fascinating phenomena including high-temperature superconductivity ([Bednorz and Müller, 1986](#)).

The Hubbard model has been shown to provide a theoretical framework to study one of the most distinctive properties of transition metal-based materials, namely, the existence of an insulating state when the electron count would imply a partially filled band (or equivalently an odd number of electrons per unit cell), in sharp qualitative contrast with the prediction of the band theory of solids. The discovery of this phenomenon dates back to [de Boer and Verwey \(1937\)](#), and it was shortly followed by the seminal proposal by N. Mott, who identified the interaction between electrons as the cause of the insulating state ([Mott and Peierls, 1937](#)). For this reason, these insulators have been called Mott insulators, and the transition between the Mott insulating state and a metal, which can be driven by chemical substitution, pressure, doping, and other control parameters, has been baptized as the Mott–Hubbard transition.

The field of transition metal oxides was revolutionized in 1986 after the discovery of its most influential members, a class of layered copper oxides displaying a superconducting state with large critical temperatures and many anomalies with respect to standard superconductors ([Bednorz and Müller, 1986](#)). In these materials, usually referred to as cuprates, the stoichiometric

compound is an antiferromagnetic Mott insulator which turns into an exotic superconductor with d-wave symmetry when doped, suggesting a close and surprising relation between the physics of Mott insulators and superconductivity.

Following an incredibly influential proposal (Anderson, 1987), the vast majority of the scientific community identified a two-dimensional Hubbard model (or the related t-J and Emery models) as the main building block to describe these systems owing to their large anisotropy and the Mott insulating character of the undoped materials. The two-dimensional modeling is justified by the large anisotropy of the cuprates and by the ubiquitous presence of copper-oxygen layers in all the different compounds of the family.

The link with high-temperature superconductivity turned the Hubbard model into a cornerstone of modern condensed matter physics and led to the creation and the development of a variety of methods aiming at a solution of the model. For the reasons we mentioned above, the community largely focused on the two-dimensional case which turned out to be a formidable challenge for theoretical investigations.

It is indeed almost impossible to summarize the collective effort to solve the two-dimensional Hubbard model in a complete and unbiased way and without making oversimplifications. The holy grail of this research has obviously been the understanding of the origin of superconductivity in a system dominated by the repulsion (Maiti and Chubukov, 2013), but several other questions have been almost equally debated, including the possible deviation from a normal Fermi-liquid of the metallic state, the existence and the origin of a pseudogap region (Lee et al., 2006), and the presence and role of quantum critical points (Sachdev, 2010) and charge instabilities (Castellani et al., 1995).

Despite the huge advances in the understanding of all these phenomena, we can not consider neither of them “solved”. For these reasons, in this manuscript we will not discuss the Hubbard model in relation with the properties of the cuprates and the investigations of the two-dimensional system, for which we refer to recent reviews and collaborations (LeBlanc et al., 2015; Schäfer et al., 2021; Qin et al., 2022; Arovas et al., 2022).

Even if the lack of a general consensus on some aspects of the phase diagram of the two-dimensional Hubbard model could lead to conclude that this impressive collective effort did not reach its goal, it certainly led to a huge advance of our understanding of strongly interacting quantum many-body systems both in terms of methodology and in terms of novel concepts which apply to a wide class of materials.

In particular, we have reached an unprecedented understanding of the physics of Mott transitions, of Mott insulators, and of the strongly correlated metallic phase. In this chapter we focus on this latter aspect, namely, the theoretical description of the Mott–Hubbard transition. In particular, we will introduce the dynamical mean-field theory, a powerful theoretical method which led to an important paradigm shift in the field of strongly correlated systems and a novel picture of the Mott transition, which represents a central starting point for the theoretical study of a number of strongly correlated materials. Among the many directions in which the DMFT picture of the Mott transition has been extended, in Section “The Mott–Hubbard transition in DMFT” we address the role of a multiorbital electronic structure and the Hund’s coupling.

Overview

The Hubbard model describes quantum particles (here spin-1/2 fermions describing the electrons of a solid) moving in a lattice and experiencing a repulsive interaction when two of them are on the same lattice site. The Hamiltonian reads

$$\hat{H} = -t \sum_{\sigma, \langle i, j \rangle} \left(\hat{c}_{i\sigma}^\dagger \hat{c}_{j\sigma} + \text{h.c.} \right) + U \sum_i \hat{n}_{i\uparrow} \hat{n}_{i\downarrow}, \quad (1)$$

where $\hat{c}_{i\sigma}$ and $\hat{c}_{i\sigma}^\dagger$ are annihilation and creation operators for fermions with spin σ on the site i of a given lattice of N sites and the operator $\hat{n}_{i\sigma} = \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma}$ is the local occupation operator for the spin species σ . The sum in the first term is restricted to pairs of nearest neighboring sites. The key control parameters are the amplitude t for a quantum tunneling (hopping) between nearest neighbor sites of a lattice and the on-site interaction between different spin species U . The other control parameter is the total filling $n = \frac{1}{N} \sum_{i\sigma} \langle \hat{n}_{i\sigma} \rangle$. The model can be seen as extremely simplified, even if absolutely nontrivial, description of materials in which narrow bands arise from orbitals which are localized around the ionic positions and the electron–electron interaction in the valence band is strongly screened by the valence electrons. As a general trend, these conditions are realized in compounds based on transition-metal atoms, where the 3d orbitals are partially filled, or rare-earth atoms with partially populated 4f levels.

The localized nature of the relevant 3d and 4f orbitals justifies to limit the hopping amplitude to nearest neighboring sites and to consider only the local components of the Coulomb interactions, as assumed in Eq. (1). The standard version of the Hubbard model (1) only contains hopping between nearest neighbor sites of the lattice, but the description of different materials usually requires to include also long-range hopping terms. We notice that the inclusion of more complete and realistic structure of hopping does not change significantly the properties of the model and it does not imply a relevant complication of the theoretical description. On the other hand, the inclusion of nonlocal interactions represents a more substantial change which can affect the physics of the model in a deeper way.

A further typical simplification assumed in Eq. (1) is to consider only one orbital per site. While this choice seems natural and justified for the high-temperature superconductors based on copper, where the electron count leads to nine electrons hosted in the

3d orbitals, many other strongly correlated materials and Mott insulators have indeed a multi-orbital electronic structure, which may lead to remarkable novel phenomena that we briefly comment in Section “Key issues”.

Despite its formal simplicity, Eq. (1) defies an exact solution except for the peculiar one-dimensional case (Lieb and Wu, 1968). As we anticipated in the introduction, the search for accurate solutions of the Hubbard model has been accelerated by the discovery of high-temperature superconductivity in the family of doped Mott insulators based on layers of copper and oxygen. The strong anisotropy of these materials prompted for an understanding of the two-dimensional Hubbard model, which became the subject of countless investigations and triggered the development of a variety of theoretical methods ranging from analytical (Arovas et al., 2022) to numerical approaches (Qin et al., 2022).

We emphasize that this collective enterprise has many facets. On one hand, a part of the community focused on fundamental aspects, among which the central role is the origin of superconductivity and the very question about how superconductivity can arise in a system dominated by the repulsive Coulomb interaction. Many other studies have instead aimed at a closer connection with the properties of superconducting cuprates, including material-dependent aspects. The immense body of work dedicated to these issues has advanced our understanding of all these phenomena, confirming to a large extent that the Hubbard model contains most of the relevant physics. Yet, the debate is still lively and open and only a few final answers have been given.

In this work we do not address these issues and we focus on a more general phenomenology which is not limited to two dimensions, namely, the interaction-driven Mott metal–insulator transition. We argue that this is the most direct and paradigmatic fingerprints of the electronic correlations driven by the large interaction, and its understanding is a fundamental step to address more specific questions, including those related to high-temperature superconductivity.

The Mott–Hubbard metal–insulator transition

The Hubbard model realizes the early proposal by N. Mott that the mutual interaction between electrons—neglected or treated approximately in the band theory of solids—is the reason for the insulating behavior of several transition-metal oxides with partially filled bands and of the transition between this Mott insulating state and a metal.

We stress that the main focus of this work is on a paramagnetic Mott transition where spatial symmetries are broken neither in the charge nor in the spin channels. In this way, we isolate the inherent effect of electron–electron interactions localizing the electrons from the gap opening associated with magnetic ordering. Even when the low-temperature region of the phase diagram features broken-symmetry solutions, the finite-temperature phase diagram will typically host a transition between a metal and a paramagnetic Mott insulator, a phenomenology which is indeed realized, for instance, in V_2O_3 (McWhan et al., 1973). In this section we discuss some basic arguments about the Mott transition and its relation with magnetism.

The very existence of the Mott insulating state, its magnetic ordering, and the metal–insulator transition can be predicted based on simple arguments even if, as we shall see, a comprehensive description and characterization of the Mott–Hubbard transition require to use advanced many-body methods able to treat the strongly correlated regime.

- In the *noninteracting limit* $U = 0$, the model (1) is solved exactly by Fourier transforming to momentum space, leading to a single band with a dispersion $\varepsilon(k)$ which depends on the chosen lattice. As a consequence, for every filling n different from zero and two, the model describes a metal with partially filled bands. This result does not change introducing long-range hopping amplitudes.
- In the *atomic limit* $t = 0$, the Hamiltonian simply counts the number of doubly occupied sites in which two electrons are present on the same site. It follows that, in the half-filling case $N = 1$, where the number of electrons is equal to the number of sites, there is an infinite number of degenerate ground states, each with one electron on each lattice site. When a small hopping $t \ll U$ is included, the degeneracy between these states is broken, but the system remains in the subspace with zero doubly occupied sites. At half-filling every hopping of an electron would imply the creation of a doubly occupied site and it is therefore forbidden, leading to a localization of the carriers which realizes nothing but the correlation-driven insulator proposed by Mott.

Thus, the half-filled Hubbard model with $N = 1$ has a metallic ground state in one extreme limit ($U \ll t$) and an insulating one in the opposite one ($U \gg t$). As a consequence, we expect a metal–insulator transition as a function of the ratio U/t to take place at zero temperature. The simple solution in the two extreme limits also provides us with a rationale of the difficulties to solve the model for arbitrary U/t . The model, in its simplicity, describes a paradigmatic competition between a hopping term, which is diagonal in momentum space and leads to delocalized electronic states, and an interaction term, which imposes constraints that favor localization in real space, where it is clearly diagonal.

This evolution of the system as U/t increases and the Mott transition can be described in terms of a progressive reduction of the quantum probability to have doubly occupied sites in the ground state D . For $U = 0$, we easily find that the total amplitude of doubly occupied states is $D = \frac{1}{4}$. As U increases, we expect less and less doubly occupied sites until for $U \rightarrow \infty$, $D = 0$. In the same process, the electron motion becomes harder and harder because every hopping that leads to a doubly occupied site is inhibited. At some critical value of U , we can expect that the coherent electronic motion is impossible and the electrons become localized as in the atomic limit. This interaction-driven localization is the essence of the Mott–Hubbard transition that we address in this work.

There is, however, a further complication, or enrichment, if we consider the possibility of broken-symmetry magnetic solutions. One can prove that, for nearest neighbor hopping and for bipartite lattices, the ground state of the Hubbard model is an antiferromagnetic insulator for every $U/t \neq 0$ (Lieb, 1989). This is measured by a finite staggered magnetization

$$m = \frac{1}{N} \sum_i (-1)^{R_i} \langle \hat{n}_{i\uparrow} - \hat{n}_{i\downarrow} \rangle. \quad (2)$$

The origin of the antiferromagnetic order can be rationalized in strong coupling $U \gg t$ through a strong coupling calculation that shows that the Hubbard model maps onto a Heisenberg model with positive exchange interaction (MacDonald et al., 1988)

$$H_{SC} = J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j, \quad (3)$$

where $\mathbf{S}_i$ is the vector of the local spin-1/2 operators describing localized electrons. The positive J favors configurations where spins of neighboring sites have opposite direction. In a bipartite lattice (a lattice which can be partitioned in two sublattices A and B in such a way that the hopping only connects A sites with B sites, such as the square and cubic lattices) one can then build a full antiferromagnetic solution on the whole lattice in which every nearest neighbor bond has the energetically favored configuration.

An antiferromagnetic insulating ground state can also be derived through a Hartree–Fock mean-field approach, which is expected to be a reasonable approximation in weak coupling. For bipartite lattices, such as the square and cubic lattices with only nearest neighbor hopping, antiferromagnetism is stable for any nonzero U . If we include next-nearest neighbor hopping, the antiferromagnetic state requires a minimum critical value of the interaction to be stabilized (Lin and Hirsch, 1987).

The weak-coupling Hartree–Fock magnetism and the strong coupling theory that we described are indeed adiabatically connected. The ground state of the Hubbard model is thus an antiferromagnet for every value of U/t . Increasing this ratio we continuously evolve from the itinerant magnetism found in Hartree–Fock (Slater, 1951) to the local moment picture of strong coupling (Sangiovanni et al., 2006).

The antiferromagnetic order is limited to $T = 0$ in two dimensions according to the Mermin–Wagner theorem (Mermin and Wagner, 1966), but it extends to finite temperature in three dimensions. Based on simple arguments, confirmed by many-body calculations (Kozik et al., 2013), the magnetic ordering temperature has the qualitative behavior reported in Fig. 1A as a dashed line, where a maximum is obtained for intermediate coupling, when neither of the two limiting approaches can be applied.

Therefore, if we focus on the ground state of the Hubbard model, the metal–insulator transition that we expected is replaced by an insulating magnetic state for any $U \neq 0$ and the only evolution happening from weak to strong coupling is a crossover between different kinds of antiferromagnetism. Nonetheless, the physics of the Mott transition that we discussed is expected to be relevant at finite temperature and in systems where the lattice frustrates magnetic ordering.

Precisely for these reasons, in the following we will mainly focus on the investigation of the Mott transition in a paramagnetic state where we discard the possibility of magnetic ordering, in order to disentangle the intrinsic Mott localization with the tendency toward magnetism. At the end of the discussion we will briefly comment about the relation between the paramagnetic Mott transition and magnetic ordering.

The history of the understanding and the theoretical description of the Mott–Hubbard transition are indeed deeply rooted with the introduction of the model. Among the most influential early attempts to study a Mott–Hubbard transition central roles are played by the methods introduced respectively by Hubbard and Gutzwiller. The former family of methods are based on truncation of the hierarchy of equations of motions for the Green’s functions, while the latter is based on the variational principle and a wave function which includes real space constraints introducing a different weight for configurations with different numbers of doubly occupied sites starting from a noninteracting wave function. The two approaches turn out to be adequate for the two opposite limits

Fig. 1 Schematic representation of the evolution of the spectral function $\rho(\omega)$ within DMFT when the ratio U/t is increased from top ($U = 0$) to bottom ($U > U_c$, in the Mott insulating phase). The vertical dotted line marks the Fermi energy. W is the noninteracting bandwidth, ZW the width of the renormalized quasiparticle peak.

of weak coupling (Gutzwiller) and strong coupling (Hubbard), but neither of them provides a unified picture which is sufficiently accurate in both limits.

Dynamical mean-field theory

A turning point in the modern understanding of the Mott–Hubbard transition has been the development of Dynamical Mean-Field Theory (DMFT) (Georges et al., 1996), a powerful approach which treats accurately both limits of weak and strong interactions. While the origin of the method lies in pioneering investigations of the limit of infinite dimensions (Metzner and Vollhardt, 1989), the best way to understand the method is a quantum (or dynamical) version of a mean-field theory, where the effect of the rest of the lattice on a single site—representative of any other site—is described by a frequency (or time)-dependent effective field which is determined self-consistently. The self-consistency is enforced by assuming a local self-energy and that the Green’s function of the effective local theory coincides with the local component of the lattice Green’s function. The dynamical nature of the effective field substantially extends the scope of the method with respect to static mean field, allowing to study intrinsically many-body phenomena, among which the Mott–Hubbard transition has been the epitome.

Starting from the Hubbard model Eq. (1), DMFT defines an effective local theory for an arbitrary site “0” associated with the effective action

$$S_{\text{eff}} = \int d\tau \int d\tau' c_{0\sigma}^\dagger(\tau) \mathcal{G}_0^{-1}(\tau - \tau') c_{0\sigma}(\tau') + U \int d\tau n_{0\uparrow}(\tau) n_{0\downarrow}(\tau), \quad (4)$$

where τ and τ' are imaginary time variables, $c_{0\sigma}^\dagger$ and $c_{0\sigma}$ are Grassman fields associated with creation and annihilation of fermions with spin σ on site 0, $n_{0\sigma} = c_{0\sigma}^\dagger c_{0\sigma}$. The effective action describes the (imaginary) time evolution of site 0 in the presence of the local repulsion, which is controlled by the dynamical Weiss field $\mathcal{G}_0^{-1}(\tau - \tau')$, which contains the effect of the rest of the lattice on site 0. Similarly to a classical mean-field theory, the dynamical mean field is determined by a self-consistency condition which requires that the Green’s function of the effective theory

$$G(\tau) = -\langle T c_{0\sigma}(\tau) c_{0\sigma}^\dagger(0) \rangle_{S_{\text{eff}}} \quad (5)$$

coincides with the local component of the lattice Green’s function. Namely, in Matsubara frequencies

$$G(i\omega_n) = \frac{1}{N} \sum_k \frac{1}{i\omega_n + \mu - \epsilon_k - \Sigma(i\omega_n)} \equiv \int d\epsilon D(\epsilon) \frac{1}{i\omega_n + \mu - \epsilon - \Sigma(i\omega_n)}, \quad (6)$$

where $\Sigma(i\omega_n)$ is the Green’s function of the effective theory, connected to the Weiss field and the Green’s function by

$$\Sigma(i\omega_n) = \mathcal{G}_0^{-1}(i\omega_n) - G^{-1}(i\omega_n). \quad (7)$$

The three Eqs. (5), (6), and (7) are a closed set of equations that allow to find a self-consistent set of $\Sigma(i\omega_n)$, $\mathcal{G}_0^{-1}(i\omega_n)$, and $G^{-1}(i\omega_n)$. The lattice enters only via the self-consistency condition which depends on the noninteracting density of states. A practical implementation of DMFT amounts to a recursive solution of the effective theory (4) computing the Green’s function (5) starting from a guess for $\mathcal{G}_0^{-1}(i\omega_n)$. Then the self-consistency is used to compute a new $\mathcal{G}_0^{-1}(i\omega_n)$ and the procedure is iterated until convergence is achieved. The solution of the effective theory usually exploits a mapping onto an impurity Hamiltonian which, for the Hubbard model, is an Anderson impurity model. Different “impurity solvers” can be used to obtain the Green’s function, each with specific advantages and disadvantages. The combined use of different solvers led the community to a complete understanding of the Mott transition in the single-band Hubbard model which represents the basis for extensions including more orbitals or partially relaxing the DMFT approximation.

As we mentioned above, DMFT is exact not only in the limit of infinite coordination (or dimensionality) but also in finite dimensionality in the opposite limits of $U = 0$ (noninteracting limit) and $t = 0$ (atomic limit). This makes the theory ideally suited to study the Mott transition, as it correctly reproduces both the opposite limits and, being exact in one well-defined limit, it is a conserving approximation. We notice in passing that DMFT remains exact in the same limit also including other local interaction terms, like exchange terms in multiorbital systems (Georges et al., 2013) or electron–phonon coupling (Capone et al., 2010).

Key issues

The Mott–Hubbard transition in DMFT

The picture of the Mott transition in DMFT is summarized in Figs. 1 and 2. In Fig. 1, we report a schematic sketch of the evolution of the local many-body one-particle spectral function

$$\rho(\omega) = -\frac{1}{\pi} \text{Im} G(\omega) \quad (8)$$

as the ratio U/t is increased. $\rho(\omega)$ can be seen as an interacting local density of states or the integral over momentum of the spectral density $A(k, \omega)$.

Fig. 2 Schematic phase diagram of the Mott transition for the half-filled single-band Hubbard model in the U/t - T plane. The *dashed red line* is the Néel temperature for antiferromagnetic order. The *blue dotted line* is the first-order Mott transition. The endpoints marked with a *blue dot* are second-order transitions. PM-M and PM-I label the paramagnetic metallic and paramagnetic insulating solutions.

For $U = 0$, the system is a metal with a half-filled band of total width W . When we increase the strength of the interaction, a part of the spectral weight shifts toward higher energy. At first this effect is essentially a broadening of the spectrum, but further increasing the interaction reveals a three-feature spectrum where a low-energy quasiparticle peak is flanked by two high-energy features centered around $\omega \simeq \pm U/2$. As the interaction grows this feature becomes clearly separated from the quasiparticle peak, which in turn shrinks. The shrinking of the low-energy feature is measured by the quasiparticle weight Z , which is obtained from the self-energy from $Z^{-1} = 1 - \frac{\partial \Sigma(\omega)}{\partial \omega}$. For $U = 0$ we have $Z = 1$, while at a critical value of the interaction U_c , Z vanishes, which means that the quasiparticle feature completely disappears, leaving behind two high-energy features which are usually referred to as Hubbard bands in connection with the original work by Hubbard. The continuous disappearance of the quasiparticle peak is the hallmark of the Mott–Hubbard transition at U_c . For a model with a semicircular density of states with half-bandwidth D (proportional to the hopping t), $U_c \simeq 2.94D$ (Bulla et al., 2001). We notice that U_c is also the largest value for which a metallic solution exists, while the insulating solution exists also for $U_{c1} < U < U_c$, with $U_{c1} \simeq 2D$, leading to a wide region of parameters where two solutions exist (Georges et al., 1996).

In Fig. 2, we show the resulting phase diagram in the plane of interaction (U/t) and temperature (T). The coexistence of solutions extends to finite temperature so that the second-order transition at zero temperature becomes at finite temperature a first-order line that ends in a finite-temperature critical point at $T \simeq 0.04D$ (Zhang et al., 1993; Georges and Krauth, 1992; Georges et al., 1996). At temperatures above the critical point, a continuous crossover connects solution with metallic and insulating character. In Fig. 2, we have also reported a sketch of the Néel temperature for a three-dimensional system. We have to stress that this curve strongly depends on the chosen lattice and on the existence of long-range hopping. For nearest-neighbor hopping the Néel temperature is indeed larger than the critical point of the Mott transition and the whole first-order line is hidden by the region of stability of the antiferromagnetic state. Yet, already for moderate values of next-neighbor hoppings, the magnetic ordering temperature is reduced and we obtain a phase diagram which resembles that of Fig. 1A, where the first-order paramagnetic Mott line emerges from the magnetic dome (Georges et al., 1996). Crucially, this phase diagram mirrors the celebrated pressure-temperature diagram of V_2O_3 (McWhan et al., 1973), which is often considered the paradigm of Mott transitions.

We summarize here some of the main new results of DMFT for which the consensus is general and many experimental confirmations have been obtained

- The Mott–Hubbard transition is of first-order at finite temperature except for the second-order endpoint without invoking the coupling with the phonons or any structural transition.
- In the strongly correlated metallic solution, metallic features and insulating features are simultaneously present at different energy scales.
- The competition with ordered phases depends on the details of the lattice, but realistic parameters provide a phase diagram close to those experimentally observed in transition-metal oxides.

The DMFT scenario for the Mott transition has been extremely influential in the field of strongly correlated systems providing the community with a solid, even if approximate, picture which is easy to visualize and compare with experiments. In particular, combining DMFT with density-functional theory (DFT) (Hohenberg and Kohn, 1964) has been extremely successful in providing a method to compute ab initio the properties of strongly correlated materials which are not accessible by standard implementations of DFT (Kotliar et al., 2006).

Another fundamental extension of DMFT is given by methods that include nonlocal dynamical correlations besides the local frequency-dependent self-energy. Several approaches have been devised and developed that can be grouped in two main categories: (i) cluster extensions of DMFT, where the single-site theory is generalized into a cluster theory and a similar self-consistent scheme is derived (Maier et al., 2005); (ii) diagrammatic extensions generalizing the DMFT construction in different directions (Rohringer et al., 2018). These approaches have a somewhat complementary character and they allowed to apply the DMFT ideas to the two-dimensional Hubbard model. As we already mentioned, this field is however still competitive and we prefer to defer the interested reader to previous review work (Maier et al., 2005; Rohringer et al., 2018).

Finally, a realistic description of most strongly correlated materials requires to go beyond the single-band Hubbard model including more than one correlated orbital in the theoretical modeling. In the next section we discuss some aspects of this physics in order to emphasize some novel phenomena characteristic of multiorbital (or multiband) Hubbard models that are simply absent in the single-band system.

Multiorbital Hubbard model

The most straightforward multiorbital extension of the Hubbard model to include M atomic orbitals (each hosting spin-1/2 fermions) is an $SU(2M)$ invariant model of the form

$$H = \sum_{i,j,m,n,\sigma} t_{ij}^{mn} \hat{c}_{im\sigma}^\dagger \hat{c}_{jn\sigma} + \frac{U}{2} \sum_i \hat{n}_i^2, \quad (9)$$

where i and j are site indices, m and n are orbital indices ranging from 1 to M , and σ is a spin label. Hence $\hat{c}_{im\sigma}^\dagger$ creates a fermion with spin σ on site i and orbital m . The Coulomb term involves the total charge on site i $\hat{n}_i = \sum_{m\sigma} \hat{c}_{im\sigma}^\dagger \hat{c}_{im\sigma}$. This term generalizes the Hubbard repulsion to the multiorbital case, simply assuming a density–density repulsion between fermions with different quantum numbers with the same strength for any pair of indices.

The first novelty of a multiorbital model is that the Mott transition is no longer limited to the case of half-filling, which here would correspond to M electrons per site, but it can take place for any integer filling $N = 1, \dots, 2M - 1$. The physical picture is quite obvious. If U is the largest energy scale, the ground state has N electrons on any site, while any charge excitation has an energy cost U . Thus, for large U , any charge excitation is forbidden and N electrons remain localized on each site.

Solving this model with DMFT does not change qualitatively the picture we described in the previous section. The metal is strongly affected by an increased U until the quasiparticle low-energy feature is destroyed and a Mott insulator is realized. There is only a quantitative dependence of the results on the number of orbitals and the filling (Florens et al., 2002).

While these result would suggest that increasing the number of orbitals has only a quantitative effect on Mott physics, it must be noted that Eq. (9) is only an approximation of the correct Hamiltonian that one obtains expanding the Coulomb interaction on a basis of localized orbitals. The generic Coulomb integral for a given site is

$$U_{mm'n'} = \int dr dr' \phi_m^*(r) \phi_n^*(r') W(r - r') \phi_{n'}(r') \phi_{m'}(r) \quad (10)$$

where $\phi_m(r)$ is a localized wave function for an electron in the orbital m (the site index is the same for every function and it is omitted), while $W(r - r')$ is the Coulomb interaction screened by the other electronic bands.

In rather general terms we can define an intra-orbital repulsion

$$U_m = \int dr dr' |\phi_m(r)|^2 W(r - r') |\phi_m(r')|^2, \quad (11)$$

an interorbital density–density repulsion

$$U'_{mn} = \int dr dr' |\phi_m(r)|^2 W(r - r') |\phi_n(r')|^2, \quad (12)$$

an exchange term

$$J_{mn} = \int dr dr' \phi_m^*(r) \phi_n^*(r') V_c(r - r') \phi_m(r') \phi_n(r) \quad (13)$$

and a pair integral

$$J'_{mn} = \int dr dr' \phi_m^*(r) \phi_m^*(r') V_c(r - r') \phi_n(r') \phi_n(r). \quad (14)$$

If we assume that the various orbitals are equivalent $U_m \equiv U$, $U'_{mn} \equiv U'$, $J_{mn} \equiv J$, and $J'_{mn} \equiv J'$. For real wave functions we also obtain $J' = J$. It follows from the definitions that $U > U' > J$. Thus the interaction Hamiltonian becomes

$$\begin{aligned} H_{int} = & U \sum_{im} \hat{n}_{im\uparrow} \hat{n}_{im\downarrow} + U' \sum_{i, m \neq n} \hat{n}_{im\uparrow} \hat{n}_{in\downarrow} + (U' - J) \sum_{i, m > n, \sigma} \hat{n}_{im\sigma} \hat{n}_{in\sigma} + \\ & -J \sum_i \sum_{m \neq n} \hat{c}_{im\uparrow}^\dagger \hat{c}_{im\downarrow} \hat{c}_{in\downarrow}^\dagger \hat{c}_{in\uparrow} + J \sum_i \sum_{m \neq n} \hat{c}_{im\uparrow}^\dagger \hat{c}_{in\downarrow} \hat{c}_{in\downarrow}^\dagger \hat{c}_{im\uparrow} \end{aligned} \quad (15)$$

If we finally assume $U' = U - 2J$, the interaction becomes invariant under orbital and spin rotations and it can be written in the form

$$H_{int} = \sum_i \left[(U - 3J) \frac{\hat{n}_i(\hat{n}_i - 1)}{2} - 2J \hat{S}_i^2 - \frac{J}{2} \hat{L}_i^2 + \frac{5}{2} J \hat{n}_i \right], \quad (16)$$

where $\hat{L}_i$ and $\hat{S}_i$ are the orbital and spin angular momentum of the electrons on site i . The final form of the interaction conveys a clear physical meaning. The first term is a Hubbard-like interaction where the repulsion U becomes $U - 3J$, while the second and third terms, both proportional to J , give rise to the first two Hund's rules. For this reason, J is called the Hund's coupling. The fourth term can be reabsorbed in a redefinition of the chemical potential.

Role of the Hund's coupling

The inclusion of the Hund's coupling J and the corresponding terms turns out to have remarkable effects on the Mott–Hubbard transition and on the correlation properties of the metallic phase which the object of current research, both in terms of model investigations and of applications to materials, including iron-based superconductors (Haule and Kotliar, 2009; de' Medici and Capone, 2017) and ruthenates (Kim et al., 2018). In this work we do not attempt a full review of this very active field of research, for which we refer to Georges et al. (2013).

We provide however some arguments to provide some intuition about the role of the Hund's coupling. In order to estimate the effect of J on the Mott transition, we can easily estimate the critical U for the Mott transition via the atomic value of the Mott gap. For a system with a filling of n electrons per site, we can compute the atomic Mott gap as the cost of exciting one electron from one site to another as $\Delta(U, J, N) = E(N + 1) + E(N - 1) - 2E(N)$, where $E(N)$ is the atomic ground state for a system of N electrons. From this quantity we can estimate U_c from the condition $\Delta(U, J, N) = W$, where W is the bandwidth.

For a single-band model, or for $J = 0$, it is easy to see that $\Delta = U$. When we include J , we obtain two radically different results for $N = M$, that is, when the system is globally half filled, and for other integer filling $N \neq M$ (de' Medici et al., 2011; Georges et al., 2013). For $N = M$, we obtain $\Delta = U + (M - 1)J$, that is, the Mott gap is increased by J . Using the above criterion, one finds that $U_c(J) = U_c(0) - (M - 1)J$. This means that the Hund's coupling reduces the critical U for the Mott transition. On the other hand, for $N \neq M$, $\Delta = U - 3J$, that is, a reduction of the Mott gap. The critical U is increased by J according to $U_c(J) = U_c(0) + 3J$.

These estimates are indeed qualitatively confirmed by DMFT calculations for that unveiled a richer scenario with respect to the single-band model. The key point is that for small values of U and J , the latter parameter cooperates with U in localizing the electrons. This is reflected by a quasiparticle weight Z that drops faster as a function of U than in the $J = 0$ case. For $N = M$, this trend is compatible with the reduction of the critical U : As a result the Mott transition occurs in a similar way as in the absence of J (or in the single-band model), only for smaller values of U . On the other hand, for $N \neq M$ we have a dichotomy in the effect of J it first favors Mott localization but, for values of the interactions, it leads shifts the critical U to larger values. We have thus a two-step localization where a first rapid reduction of the electronic mobility is followed by a large region where Z is almost flat before a Mott transition takes place (de' Medici et al., 2011). This interaction-resistant metal has been called a Hund's metal (Haule and Kotliar, 2009). The investigation of the properties of Hund's metals is currently a very active field of research encompassing fundamental research and applications to different materials, including iron-based superconductors (de' Medici et al., 2014; de' Medici and Capone, 2017), ruthenates (Kim et al., 2018). We notice in passing that the anomalous phonon-driven superconductivity of alkali-doped fullerides is understood in the terms of a model of the form (16) with a negative Hund's coupling $J = -|J|$ arising from electron–phonon coupling (Capone et al., 2009; Nomura et al., 2015).

Another quite general phenomenon which is realized in multiorbital correlated systems, especially when the Hund's coupling is sizable, is orbital-selective Mott physics. An orbital-selective Mott insulator is defined as a system in which the electrons in some orbitals are Mott localized, while those of other orbitals remain itinerant (Vojta, 2010). The metallic region close to an orbital-selective Mott transition is characterized by orbital-selective correlations, that is, the coexistence of carriers with remarkably different correlation properties. A large body of experimental data on iron-based superconductors can indeed be understood within this framework, both in the metallic normal state (de' Medici et al., 2014; Capone, 2018; Kostin et al., 2018) and in the superconducting state, in which orbital-selective pairing has been observed (Sprau et al., 2017).

Conclusion

In this work we have outlined the scenario of the Mott–Hubbard transition obtained within DMFT (Georges et al., 1996). Regardless of the accuracy of the method, the DMFT description of the Mott transition can be considered as a paradigm of “pure” Mott physics because the method treats accurately the competition between the delocalizing effect of the hopping term and the blocking effect of the Hubbard local repulsion and it allows to disentangle this intrinsic Mott localization with the tendency to form spatially ordered phases, like the antiferromagnetic phase of the single-band Hubbard model. In this sense, we consider the DMFT scenario as a paradigm to be used as the basic backbone of calculations including nonlocal dynamical correlations and/or more realistic descriptions of materials.

The picture that emerges within DMFT is richer than previously expected. The evolution from a standard metal to a paramagnetic Mott insulator is characterized by the development of a strongly correlated metallic state in which the low-energy properties of the system are those of a strongly renormalized Fermi liquid, while the high-energy behavior is similar to a precursor of an insulator. The Mott–Hubbard transition is associated with the disappearance of the low-energy quasiparticle features, leaving behind a preformed gap (Georges et al., 1996).

At finite temperature, the transition becomes a first-order line which ends in a critical point (Zhang et al., 1993; Georges and Krauth, 1992; Georges et al., 1996). The first-order character of the Mott transition is a remarkable prediction of DMFT which is

actually in agreement with the phenomenology of transition-metal oxides, where a first-order line emerges from a magnetic low-temperature state. This demonstrates that the first-order character of the transition is of electronic origin, in contrast with previous expectations that the coupling with the lattice was a necessary condition to make the transition discontinuous.

The DMFT scenario of the Mott transition and its prediction on several observables have been verified in three-dimensional strongly correlated materials (McWhan et al., 1973; Furukawa et al., 2015), leading to a substantial advance both in our understanding and in our ability to accurately compute the properties of this class of materials.

However, a full account of the properties of many materials requires to relax some of the approximations behind the single-band Hubbard model and/or to address the role of low dimensionality. In particular, a realistic description of most correlated materials requires to include multiple low-energy orbitals. This extension is far from trivial, in particular when the Hund's exchange is not small (Georges et al., 2013). In this case, novel phenomena like a two-step Mott localization and orbital-selective Mott physics have been identified in the recent years.

Finally, several methods have been proposed to extend DMFT including nonlocal correlation effects. Different approaches, ranging from cluster extensions (Maier et al., 2005) to diagrammatic methods focusing on two-particle correlations (Rohringer et al., 2018) are currently being developed in order to close the gap that separates us from a complete theory of the Mott transition in two dimensions.

Abstract

Electron quantum optics recently emerged as a new branch of condensed matter physics aimed at creating, manipulating and detecting electronic wave-packets ballistically propagating along one-dimensional mesoscopic channels. Here, theoretical tools elaborated in the framework of the conventional quantum optics based on photons have been reconsidered in order to properly describe interferometric experiments showing an interplay between the fermionic nature of the electrons and the ubiquitous many-body interaction among them. This allowed a direct comparison between the predictions derived within the Luttinger liquid picture for interacting electrons in one-dimension and the experimental observations. This Chapter will provide an overview on this subject, with main focus on the case of wave-packets generated by means of time-dependent voltage pulses.

Key points

- From quantum optics to electron quantum optics: the dictionary.
- Experimental milestones: electron partitioning and collisional interferometry.
- Effects of interaction: the Luttinger paradigm in action.
- Strongly correlated systems: crystallization in the time domain.

Introduction

The technological advancement in the generation, control and measurement of individual electronic degrees of freedom in solid-state devices opened the way to the development of Electron Quantum Optics (EQO) (Bocquillon et al., 2013). This branch of condensed matter physics aims at realizing quantum optics-like experiments with electrons ballistically propagating along mesoscopic channels and has been characterized since the beginning by a remarkable synergy between experimental investigations and theoretical analysis.

In this direction, the edge channels of an Hall bar in the quantum regime represent the ideal candidate for the realization of one-dimensional chiral wave-guides (Das Sarma and Pinczuk, 2004). Moreover, thanks to the applications of electrostatic gates, these states can be put in contact realizing a Quantum Point Contact (QPC), which mimics the functioning of a beam-splitter. The last ingredient to complete this translation from the photonic to the electronic domain is provided by on-demand single-electron sources. Even if various techniques have been proposed to implement this essential building block, two of them emerged as more promising. The first is based on a quantum dot coupled to the Hall bar whose Fermi level is periodically driven above and below the one of the outer channel of the Hall bar in such a way to trigger the controlled injection of electrons and holes (Fève et al., 2007). The second requires the application of a periodic drive directly on the one-dimensional channels. Despite apparently simpler, this approach needs an extremely high level of control on the form of the applied voltage. Indeed, only a properly quantized train of voltage pulses with Lorentzian profile in time is able to guarantee the injection of purely electronic states, with no additional spurious particle-hole pairs, usually called Levitons (Levitov et al., 1996; Glatli and Rouleau, 2017).

Thanks to the tools discussed above, two seminal electron interferometers have been realized within a condensed matter setting (Bocquillon et al., 2013). When only one train of excitations reaches the QPC, the measurement of the outgoing current fluctuations allows to access a particle partitioning reminiscent of what observed in the Hanbury-Brown-Twiss (HBT) intensity interferometer. Moreover, when two trains are injected on the opposite sides of the QPC, the electronic analogous of the Hong-Ou-Mandel (HOM) collisional interferometer is achieved. It is characterized by the presence of a dip in the current fluctuations for synchronized

injections, signature of the fact that identical fermionic excitations cannot emerge on the same outgoing channel due to the Pauli principle. A similar feature, involving the number of coincidences instead of the fluctuations, represents the footprint of its photonic counterpart.

Despite this simple free-electron picture provides important hints of the physics at work in these devices, for technical reasons experiments in this domain are usually carried out with edge states at filling factor $\nu = 2$ or even higher, where the Coulomb interaction among the edge channels cannot be neglected. This represents a further major difference between the photonic and the electronic cases and needs to be carefully taken into account. The conventional way to do this is based on the Luttinger liquid description, which properly describes interacting one-dimensional systems, replacing the standard Fermi liquid picture valid at higher dimensions (Giamarchi, 2003). While this interaction only marginally affects the functioning of the HBT interferometer, its role dramatically emerges in HOM interferometers as we will see in the next Sections.

Even more interesting are the effects of electron-electron interaction in strongly correlated systems such as the fractional quantum Hall edge states (Das Sarma and Pinczuk, 2004). Here, the HOM noise generated by the collision of Levitons carrying a charge multiple of the electron one shows the emergence of various side dips (Ronetti et al., 2018). These can be interpreted in terms of an interaction-induced crystallization of the injected wave-packets, real-time analog of what observed in Luttinger liquids confined in a potential well.

The present Chapter aims at providing a review of the role of interaction in electron quantum optics addressing in detail the points sketched above.

Wave-guides, beam-splitters and on-demand single-electron sources

In quantum optics experiments individual photonic degrees of freedom are injected into wave-guides, such as optical fibers, and manipulated using beam-splitters, realized for example by means of half-silvered mirrors. Starting from these elementary building blocks various interferometers have been realized and used to investigate the coherence property of light, the wave/particle nature of the photons and the consequences of their bosonic statistics.

The possibility to realize analogous experiments using electrons ballistically propagating along one-dimensional mesoscopic channels in solid-state devices has been investigated since the nineties. A particularly suitable platform to implement this translation from the photonic to the electronic domain is represented by the edge states of the quantum Hall effect (Das Sarma and Pinczuk, 2004). Here, a very clean two-dimensional electron gas realized in GaAs/AlGaAs heterostructures, placed in an intense magnetic field (~ 10 T) and at low temperature (below ~ 1 K), is characterized by a chiral current flowing only along one-dimensional channels localized at the edge of the Hall bar. Under these conditions, the electron propagation is unaffected by impurity-induced random backscattering, leading to impressive coherence lengths ($\sim 20 \mu\text{m}$) at cryogenic temperatures (~ 20 mK). Moreover, thanks to a properly designed electrostatic confinement induced by gates, the electron gas can be locally pinched off. This allows to approach the opposite edge of the Hall bar creating a QPC, characterized by a controllable probability of backscattering for the electrons. The experimental set-up described so far offers the ideal conditions for the realization of the electronic counter-part of both wave-guides and beam-splitters (see Fig. 1 below).

However, the realization of on-demand sources of controlled electronic wave-packets required additional experimental effort. In this direction, two main technologies emerged during the years. The first, developed by the experimental group of the Laboratoire Pierre Aigrain in Paris (Fève et al., 2007), is based on a quantum dot capacitively coupled to the outer channels of an Hall bar. By periodically driving the Fermi level of this confined system and properly tuning the coupling, it is possible to inject into the edge channel one electron and one hole per period T . The wave-packets generated in this way are characterized by a Lorentzian profile in the energy domain (Bocquillon et al., 2013).

A conceptually easier, but experimentally more challenging, way to realize an on-demand electron source has been implemented by the experimental Nanoelectronics group in Saclay (Glattli and Rouleau, 2017). It consists in the direct application of a periodic drive to a mesoscopic channel. According to theoretical analysis (Levitov et al., 1996), the form of this voltage need to be chosen carefully. In particular, a train of Lorentzian voltage pulses in time of the form (from now on we assume $\hbar = 1$)

Fig. 1 Cartoon view of a two-dimensional electron gas (light blue) subject to a perpendicular magnetic field $\vec{B}$. In the quantum regime, two edge channels (outer in red and inner in blue) propagate along the boundary of the sample and can be approached by means of a gate voltage (V_g).

Fig. 2 Injection in a mesoscopic channel of electronic wave-packets with typical width $2\tau_0$, through the application of a periodic train of Lorentzian voltage pulses in time $V(t)$.

$$V(t) = \frac{q}{e} \sum_{m=-\infty}^{+\infty} \frac{2\tau_0}{(t - mT)^2 + \tau_0^2} \quad (1)$$

with e charge of the electron and q a real parameter, leads to the periodic injection (again with period T) of purely electronic Lorentzian wave-packets of width τ_0 in the time domain in the case of integer values q (see Fig. 2 below).

This is a direct consequence of the quantization of edge conductance, given by $G = e^2/(2\pi)$, as can be seen by the simple chain of relations involving the current $I(t)$ flowing along the edge, namely

$$Q = \frac{1}{T} \int_{-\frac{T}{2}}^{+\frac{T}{2}} dt I(t) = \frac{1}{T} \int_{-\frac{T}{2}}^{+\frac{T}{2}} dt \frac{e^2}{2\pi} V(t) = qe. \quad (2)$$

In addition, if one chooses an integer value of q the created excitations, called Levitons, are characterized by the absence of spurious additional particle-hole contributions and less affected by the interaction with respect to other injected pulses. This kind of source is therefore able to generate clean and robust electronic wave-packets.

The two on-demand single-electron sources discussed above are complementary, showing a Lorentzian behavior in the energy and time domain respectively, and opened the way to the first seminal interferometric experiments in the field of EQO.

Hanbury-Brown-Twiss and Hong-Ou-Mandel interferometry with electrons

We start this discussion with a description of the electronic version of the HBT interferometer. In ideal conditions, a controlled train of electrons (and eventually holes) is generated by means of one of the two sources discussed above and injected into a quantum Hall edge channel. Once arrived at a QPC they have a probability $\mathcal{T}$ to be transmitted along the same edge and a probability $\mathcal{R} = 1 - \mathcal{T}$ to be reflected on the opposite edge, the constraint being imposed by particle number conservation (see Fig. 3 below).

To be more precise, the action of the QPC on free electrons is encoded by the unitary scattering matrix

$$s = \begin{pmatrix} \sqrt{\mathcal{R}} & i\sqrt{\mathcal{T}} \\ i\sqrt{\mathcal{T}} & \sqrt{\mathcal{R}} \end{pmatrix} \quad (3)$$

in such a way that the outgoing annihilation fermionic operators (in channels 3 and 4) are connected to the incoming ones (in channels 1 and 2) through the simple relation

$$\begin{pmatrix} c_3 \\ c_4 \end{pmatrix} = s \begin{pmatrix} c_1 \\ c_2 \end{pmatrix}. \quad (4)$$

Notice that great care is devoted by experimentalists to find a proper working point of the QPC where $\mathcal{T}$ and $\mathcal{R}$ are energy independent. This guarantees that wave-packets with a finite spread in energy are not improperly distorted at this level. According to this we have suppressed all the energy dependence in (3) and (4).

The excitations emerging from the QPC are then detected in one of the outgoing edge channels in such a way to investigate the partitioning associated with their corpuscular nature. Assuming, for sake of clarity, a unique excitation injected in the incoming

Fig. 3 Cartoon view of a set-up for partitioning and collisional experiments. Excitations flowing along the incoming channels 1 and 2 (green arrows) reach the central QPC (cyan) and emerge in the outgoing channels 3 and 4 (red arrows).

channel 1 one has obviously an average number of excitations $\langle N_1 \rangle = \langle c_1^\dagger c_1 \rangle = 1$ and $\langle N_2 \rangle = \langle c_2^\dagger c_2 \rangle = 0$ in the incoming channels with no fluctuations: $\langle (\Delta N_1)^2 \rangle = \langle (\Delta N_2)^2 \rangle = 0$, with $\Delta N_{1,2} = N_{1,2} - \langle N_{1,2} \rangle$. Due to the action of the QPC, in the outgoing channels one has $\langle N_3 \rangle = \mathcal{R}$, $\langle N_4 \rangle = \mathcal{T}$ with fluctuations

$$\langle (\Delta N_3)^2 \rangle = \langle (\Delta N_4)^2 \rangle = -\langle \Delta N_3 \Delta N_4 \rangle = \mathcal{R}\mathcal{T}. \quad (5)$$

The above expression characterizes the random partitioning of corpuscular excitations at the level of the QPC and is usually indicated as partition noise.

Even more interesting is the situation for what it concerns the electronic translation of the HOM interferometer. This consists in a collisional experiment in which two identical trains of excitations are injected, with a tunable delay t_D , on the opposite sides of a QPC (channels 1 and 2) and detected in the outgoing channels. For a time delay longer than the typical width of the wave-packets in time the partitioning of the two trains of excitations at the QPC is independent and one recovers the HBT phenomenology discussed above. However, for synchronized injections ($t_D = 0$) the colliding fermionic excitations are forced to always emerge on the opposite sides of the QPC. Also in this case we can understand this phenomenology considering the action of the QPC scattering matrix (3). In this case one has $\langle N_1 \rangle = \langle N_2 \rangle = 1$ in the incoming channels, again with no fluctuations: $\langle (\Delta N_1)^2 \rangle = \langle (\Delta N_2)^2 \rangle = 0$. In the outgoing channels one has $\langle N_3 \rangle = \langle N_4 \rangle = 1$ with

$$\langle (\Delta N_3)^2 \rangle = \langle (\Delta N_4)^2 \rangle = -\langle \Delta N_3 \Delta N_4 \rangle = 0. \quad (6)$$

This is a direct consequence of the Pauli principle which prevents two identical electrons to emerge in the same outgoing channel, leading to an anti-bunching effect. In order to further strengthen this statement, we observe that in a photonic HOM experiments the excitations always bounch with the emergence of pairs of photons on one of the two outgoing branch of the interferometer, namely (Bocquillon et al., 2013)

$$\left\langle \left(\Delta N_3^{(ph)} \right)^2 \right\rangle = \left\langle \left(\Delta N_4^{(ph)} \right)^2 \right\rangle = -\left\langle \Delta N_3^{(ph)} \Delta N_4^{(ph)} \right\rangle = 4\mathcal{R}\mathcal{T}. \quad (7)$$

In order to go beyond this simplified picture and to better understand the relevant physics at work in actual experiments, we need to properly theoretically address what can be directly measured in electronic interferometers. Indeed, while in quantum optics experiments the measurement of photo-counting and coincidences as a function of time is possible thanks to detectors placed in the outgoing branches of the interferometer, the sensitivity of their solid-state counterparts is not enough to achieve a real-time counting of outgoing excitations. To overcome this issue, experimentalists in the field investigate the current correlations, in particular the cross-correlated zero frequency noise averaged over the period T of the injection, which is defined as

$$S = \int_{-\frac{T}{2}}^{+\frac{T}{2}} \frac{dt}{T} \int_{-\infty}^{+\infty} d\tau \left[\left\langle I_3 \left(t + \frac{\tau}{2} \right) I_4 \left(t - \frac{\tau}{2} \right) \right\rangle_{\mathcal{Q}} - \left\langle I_3 \left(t + \frac{\tau}{2} \right) \right\rangle_{\mathcal{Q}} \left\langle I_4 \left(t - \frac{\tau}{2} \right) \right\rangle_{\mathcal{Q}} \right]. \quad (8)$$

In the above equation I_α is the operator associated to the current flowing along the outgoing channel $\alpha = 3, 4$ and the expectations values are taken with respect to the initial density matrix $\mathcal{Q}$, which takes into account the injection of additional excitations with respect to the Fermi level of the edge channel.

The noise discussed above is directly related to the fluctuations of the charge outgoing from the QPC in a given period. According to what discussed in (3) and (4) it is possible to connect the fluctuations of the outgoing currents with the incoming ones. This leads to the decomposition

$$S = S^{\text{FS}} + \sum_{\alpha=1,2} S_\alpha^{\text{HBT}} + S^{\text{HOM}}(t_D). \quad (9)$$

The first terms (S^{FS}) only depends on the properties of the many-body Fermi sea of the edge channels when the electron source are switched-off, namely temperature and dc bias, and is typically subtracted in experiments. The second term is the sum of two contributions of the form

$$S_\alpha^{\text{HBT}} = \mathcal{R}\mathcal{T} \frac{e^2}{2\pi} \int_{-\frac{T}{2}}^{+\frac{T}{2}} \frac{dt}{T} \int_{-\infty}^{+\infty} d\omega \Delta W_\alpha(t, \omega) \left[1 - 2f_\mu(\omega) \right]. \quad (10)$$

Here, we have introduced the Fermi distribution f_μ at fixed temperature and chemical potential μ , supposed the same for both edges of the Hall bar for sake of simplicity, and the excess Wigner function (Ferraro et al., 2013) defined as

$$\Delta W_\alpha(t, \omega) = v \int_{-\infty}^{+\infty} d\tau e^{i\omega\tau} \left[\left\langle \Psi_\alpha^\dagger \left(t - \frac{\tau}{2} \right) \Psi_\alpha \left(t + \frac{\tau}{2} \right) \right\rangle_{\mathcal{Q}} - \left\langle \Psi_\alpha^\dagger \left(t - \frac{\tau}{2} \right) \right\rangle_{\mathcal{F}} \left\langle \Psi_\alpha \left(t + \frac{\tau}{2} \right) \right\rangle_{\mathcal{F}} \right]. \quad (11)$$

This latter quantity completely characterizes the time-energy profile of the excitations injected into the channel $\alpha = 1, 2$. In the above expression, v is the propagation velocity of the excitations along the edge channels,

$$\Psi_\alpha(t) = \frac{1}{\sqrt{v}} \int_{-\infty}^{+\infty} d\omega c_\alpha(\omega) e^{-i\omega t} \quad (12)$$

is the time representation of the annihilation operator for an electron in the incoming channel α and with F we indicate the average taken with respect to the Fermi sea in absence of injected excitations.

Finally, the last term in (9) reads

$$S^{\text{HOM}}(t_D) = -\mathcal{R}T \frac{e^2}{\pi} \int_{-\frac{T}{2}}^{\frac{T}{2}} \frac{dt}{T} \int_{-\infty}^{+\infty} d\omega \Delta W_1(t, \omega) \times \Delta W_2(t + t_D, \omega) \quad (13)$$

and characterizes the overlap between excitations injected in the two incoming channels with a controlled delay t_D . Notice that this contribution goes to zero when the delay exceeds the typical time width of the injected wave-packets.

According to the above considerations, an HBT experiment is properly described by a noise contribution of the form (10). It characterizes the partition of the excitations at the QPC discussed in (5) and described here by the excess Wigner function, but takes into account also a suppression of the noise due to the unavoidable Pauli repulsion between the incoming excitations and the ones already present in the edge channels described by a Fermi sea at a cryogenic but finite temperature.

For what it concerns HOM measurements, the ratio

$$\mathcal{Q}(t_D) = \frac{S_1^{\text{HTB}} + S_2^{\text{HTB}} + S^{\text{HOM}}(t_D)}{S_1^{\text{HTB}} + S_2^{\text{HTB}}} \quad (14)$$

is typically reported (Bocquillon et al., 2013; Glatli and Roulleau, 2017). As an example, in the case of a Leviton carrying a charge $q = 1$ one can find the analytical expression for the above ratio

$$\mathcal{Q}(t_D) = \frac{\sin^2\left(\pi \frac{t_D}{T}\right)}{\sinh^2\left(2\pi \frac{\tau_0}{T}\right) + \sin^2\left(\pi \frac{t_D}{T}\right)}. \quad (15)$$

It shows a dip reaching zero at $t_D = 0$, which is consistent with the previously discussed idea of total suppression of the current fluctuations in case of synchronized collisions associated to the certainty of finding exactly one excitation in each outgoing channel as a consequence of the Pauli repulsion. Moreover, it asymptotically approaches one, in the limit $\tau_0 \ll T$, recovering the HBT physics. Notice that, differently from the HBT signal, the HOM one is only marginally affected by thermal effects that will be neglected in the following.

The simple analysis given so far, inherently based on a free fermion picture, is only able to provide a qualitative description of the observations. Indeed, despite the HBT behavior is typically well depicted, discrepancies in the form of the HOM dip with respect to the reported theoretical results are observed (Bocquillon et al., 2013). This is related to the fact that measurement are typically carried out at filling factors $\nu = 2$, where two channels co-propagate at edge of the Hall bar. Electron-electron interaction between them need to be carefully taken into account in order to accord theory and experiments. In the following, we will discuss how to handle inter-channel interaction in the framework of the chiral Luttinger liquid picture.

Luttinger liquid description of interacting quantum Hall edge channels

Non-interacting electrons form a Fermi gas characterized by infinity long-lived electron and hole excitations. In two and three dimensions this picture can be extended to include interacting cases, leading to the notion of Fermi liquid elaborated by L. D. Landau during the fifties. Here, virtual particle-hole pairs dress the excitations with the consequent renormalization of the physical parameters, such as the effective mass, and the emergence of a finite lifetime for the excitations. Despite this, these quasi-particles maintain their individual nature. Radically different is the situations for interacting one-dimensional electrons. Here, due to the geometrical constraint, every individual degree of freedom immediately turns into density fluctuations of the overall system, leading a failure of the Fermi liquid description. These collective excitations, corresponding to electron-hole pairs close to the Fermi energy, are properly described in term of a bosonic theory known as the Luttinger liquid model (Haldane, 1981; Giamarchi, 2003). In the following, we will investigate the dynamics of the edge states of a quantum Hall bar at filling factor $\nu = 2$ in this framework.

On each edge of the Hall bar, the two co-propagating channels (indicated in the following with a and b respectively) interact capacitively along a region of finite length L via screened Coulomb interaction (see Fig. 4 below).

Fig. 4 Scheme of a quantum Hall edge state at filling factor $\nu = 2$. Here, the two channels a and b interact with a short range capacitive coupling u over a finite length L .

Consistently to experimental observations no electron tunneling occurs between the two channels. Due to the presence of the magnetic field, this situation is well represented by a chiral version of the Luttinger liquid theory in which the interacting one-dimensional edge channels are described in terms of bosonic modes usually called edge-magnetoplasmons (Wen, 1995). The Hamiltonian density of the systems can be written as

$$\mathcal{H} = \frac{1}{4\pi} \sum_{i,k=a,b} \mathcal{V}_{i,k} [\partial_x \phi_i(x) \partial_x \phi_k(x)] \quad (16)$$

with

$$\mathcal{V} = \begin{pmatrix} v & u \\ u & v \end{pmatrix} \quad (17)$$

and where the bosonic modes ϕ_i are related to the electron particle density operator of each channel through

$$\rho_i(x) = \frac{1}{2\pi} \partial_x \phi_i(x) \quad i = a, b. \quad (18)$$

The annihilation operator for an electron at point x of one of the two channels can be written in this picture in the form

$$\Psi_i(x) = \frac{\mathcal{F}_i}{\sqrt{2\pi\xi}} e^{-i\phi_i(x)} \quad i = a, b \quad (19)$$

with ξ a finite length cut-off and $\mathcal{F}_i$ playing the role of Klein factors.

In (16), for sake of simplicity, we have assumed identical propagation velocity v for both the excitations along the two edge channels and we have indicated with u the intensity of their capacitive coupling. Under these conditions the full interacting problem can be easily diagonalized through a rotation in the field space. The full Hamiltonian density then becomes

$$\mathcal{H} = \frac{1}{4\pi} \sum_{\beta=\rho,\sigma} v_\beta [\partial_x \phi_\beta(x)]^2 \quad (20)$$

in terms of the rotated fields

$$\begin{aligned} \phi_\rho(x) &= \frac{1}{\sqrt{2}} [\phi_a(x) + \phi_b(x)] \\ \phi_\sigma(x) &= -\frac{1}{\sqrt{2}} [\phi_a(x) - \phi_b(x)]. \end{aligned} \quad (21)$$

These fields are associated with a fast charged mode ($\phi_\rho(x)$) and a slow dipole mode ($\phi_\sigma(x)$) propagating with velocities $v_{\rho,\sigma} = v \pm u$, respectively.

Focusing, for pedagogical reasons, on the case of Levitons injection one can model the electron source as an ohmic contact which couples the outer channel a with a time-dependent voltage source $V(t)$. This leads to an additional term in the Hamiltonian density of the form

$$\mathcal{H}_V = eV(t)\rho_a(x)\Theta(-x), \quad (22)$$

where we have assumed a macroscopic contact from $-\infty$ to $x = 0$ in correspondence of the starting of the interacting region. This allows to fix the proper initial conditions for the quantum fields at the beginning of the interacting region. Taking into account the transformation in (21) and solving the complete dynamics of the system, the voltages outgoing from the interacting region and reaching the QPC in the channels a and b respectively are related to the incoming one through

$$\begin{aligned} V'_a(t) &= \frac{1}{2} [V(t - \tau_\rho) + V(t - \tau_\sigma)] \\ V'_b(t) &= \frac{1}{2} [V(t - \tau_\rho) - V(t - \tau_\sigma)], \end{aligned} \quad (23)$$

with $\tau_{\rho,\sigma} = v_{\rho,\sigma}/L$ times of flight required by the charged and dipole mode to cross the interacting region. This leads to the fractionalization of the voltage pulse illustrated in Fig. 5 below.

The consequences of this phenomenology on the form of the HOM dip will be discussed in the following.

Fig. 5 Cartoon view of the fractionalization of a peaked voltage profile injected into the a channel, crossing an interacting region and reaching a QPC.

Effects of interaction in the Hong-Ou-Mandel profile: The Leviton case

According to what reported in (23) it is possible to Fourier expand both the HBT and the HOM contributions to the noise. The ratio in (14) can then be written, at zero temperature, as

$$\mathcal{Q}(t_D) = \frac{\sum_{l=-\infty}^{+\infty} \left| \sum_m \bar{p}_{l+m}(q) \bar{p}_m^*(q) e^{im\Omega t_D} \right|^2 |l|}{2 \sum_{l=-\infty}^{+\infty} [|\bar{p}_l(q)|^2 |l+q|]} \quad (24)$$

where we have made explicit the dependence with respect to the number of the injected excitations q . In the above expression we have introduced $\Omega = 2\pi/T$ and the quantity

$$\bar{p}_l(q) = \sum_{n=-\infty}^{+\infty} p_{l-n}\left(\frac{q}{2}\right) p_n\left(\frac{q}{2}\right) e^{i\Omega\tau_\rho(l-n)} e^{i\Omega\tau_\sigma n} \quad (25)$$

with

$$p_l(z) = z \sum_{s=0}^{+\infty} \frac{(-1)^s \Gamma(z+l+s) e^{-2\pi\tau_0(2s+l)/T}}{\Gamma(z+1-s)\Gamma(1+s)\Gamma(1+l+s)} \quad (26)$$

giving the probability amplitude for an electron to absorb ($l > 0$) or emit ($l < 0$) l photons in the case of Lorentzian voltage pulse in time (Glatli and Roulleau, 2017).

We consider now, for sake of simplicity, the ratio $\mathcal{Q}$ evaluated in a symmetrical set-up with respect to the QPC, namely a configuration where the lengths of the two interacting regions in the incoming channels are identical. When interaction is present, by changing the time delay t_D between the right and the left moving trains of excitations, we find three characteristic signatures in the noise profile (see Fig. 6 below).

At $t_D = 0$ a central dip appears for both the free electron case described by (15) and the interacting case, while two previously absent side-dips emerge at a position $t_D = \pm |\tau_\rho - \tau_\sigma|$. The shape of these three dips is reminiscent of the Lorentzian profile in time of the wave-packet of the injected excitations while their width depends on its typical timescale (Rebora et al., 2020).

This interference pattern can be easily understood in terms of the Luttinger liquid picture discussed in the previous Section. After injection, the electrons are fractionalized into two modes: a slow dipole mode and a fast charged mode (see Fig. 5). The central dip, which corresponds to the symmetric situation of simultaneous injection of electrons, start from zero because these identical excitations reach the QPC at the same time. The destructive interference is responsible for the appearance of side-dip structures. Indeed, when $t_D = \pm |\tau_\rho - \tau_\sigma|$ the fast right moving mode and the slow dipole mode reach the QPC at the same time.

Even more dramatic features are predicted to appear in strongly interacting systems like fractional quantum Hall edge channels. These will be discussed in the following Section.

Crystallization of Levitons in the fractional quantum Hall regime

A prototypical example of strongly correlated electron systems is represented by fractional quantum Hall states with filling factor belonging to the so called Laughlin sequence, namely with $\nu = 1/(2n+1)$ with $n \in \mathbb{N}$ (Das Sarma and Pinczuk, 2004). According to the chiral Luttinger liquid picture discussed above (Wen, 1995), the up u and down d edge states of the Hall bar in

Fig. 6 Ratio $\mathcal{Q}$ for Lorentzian voltage pulses, carrying unitary charge $q = 1$, as a function of t_D/T for a symmetric setup shown for the non-interacting (black curve) and the interacting case (red curve). Other parameters are: $\tau_0/T = 0.05$, $v_\rho = 4 \times 10^5$ m/s, $v_\sigma = 1.8 \times 10^5$ m/s and $L = 2$ μm .

this regime can be both described in terms of a single chiral bosonic mode for each edge. The low energy effective Hamiltonian density for the system reads

$$\mathcal{H} = \frac{v}{4\pi} \sum_{j=u,d} \left[\partial_x \phi_j(x) \right]^2 \quad (27)$$

with particle density operators given by

$$\rho_{u,d}(x) = \pm \frac{\sqrt{v}}{2\pi} \partial_x \phi_{u,d}(x). \quad (28)$$

We assume again that a Lorentzian train of voltage pulses $V(t)$ is applied to one (HBT configuration) or both (HOM configuration) the channels by means of a capacitive coupling between the channel and an ohmic contact.

Differently from what done before, in this case it is no more possible to assume a non-interacting picture for tunneling of excitations at the level of the QPC and the scattering matrix derived from it. Therefore, a more convenient way to handle the problem requires a perturbative approach. As an additional, despite very interesting, complication in the present case the more relevant tunneling process is represented by emergent fractionally charged excitation with charge $e^* = ve$ whose annihilation is described in terms of the operator $\tilde{\Psi}_{u,d}(x)$. Their tunneling from u to d and vice versa is taken into account by the Hamiltonian contribution (Wen, 1995)

$$\mathcal{H}_\Lambda = \Lambda \tilde{\Psi}_u^\dagger(x) \tilde{\Psi}_d(x) \delta(x) + \text{H.c.} \quad (29)$$

$$= \frac{\Lambda}{2\pi\zeta} e^{-i\sqrt{v}\phi_u(x)} e^{i\sqrt{v}\phi_d(x)} \delta(x) + \text{H.c.} \quad (30)$$

Here, we have introduced the tunneling amplitude Λ . Taking into account the chiral propagation of the modes along the edge, which relates the space coordinate x with the time t , the backscattering current operator due to the quasiparticles is given by

$$I_B(t) = ie^* \frac{\Lambda}{2\pi\zeta} e^{-i\sqrt{v}\phi_u(t)} e^{i\sqrt{v}\phi_d(t)} + \text{H.c.} \quad (31)$$

Starting from this, it is possible to evaluate the noise perturbatively in Λ . In the following we will stop at the leading order in this expansion.

In case of identical injection on the two incoming channels, the two identical HBT contributions to the noise can be given again in terms of a Fourier series, namely

$$S_z^{\text{HBT}}(q) = -2(e^*)^2 \frac{|\Lambda|^2}{(2\pi\zeta)^2} \sum_{l=-\infty}^{+\infty} |p_l(q)|^2 \times \\ \times [P_{2v}((q+l)\Omega) + P_{2v}(-(q+l)\Omega)] \quad (32)$$

where we have introduced the function

$$P_g(\omega) = \frac{2\pi}{\Gamma(g)\omega_c^g} x^{g-1} \Theta(\omega) \quad (33)$$

with $\Gamma(g)$ the Euler's Gamma function of argument g and $\omega_c = v/\zeta$

In the case of a train of Lorentzian voltage pulses, the HBT noise shows a Poissonian behavior each time q is an integer (Rech et al., 2017). This is another signature of the fact that integer charged Levitons are robust excitations also in presence of strong interaction.

In the HOM case, considering the injection of two identical train of excitations carrying the same charge q on the two side of the Hall bar and following the same procedure we have used for the HBT noise, we get

$$S^{\text{HOM}}(t_D) = -2(e^*)^2 \frac{|\Lambda|^2}{(2\pi\zeta)^2} \sum_{l=-\infty}^{+\infty} \left| \sum_m p_{l+m}(q) p_m^*(q) e^{im\Omega t_D} \right|^2 \\ \times [P_{2v}(l\omega) + P_{2v}(-l\omega)]. \quad (34)$$

The profile of the corresponding ratio $\mathcal{Q}$ as a function of the injection delay and for different values of injected charge q is shown in Fig. 7 below. It is strongly different with respect to what shown in both the free fermion case and the interacting case at filling factor $\nu = 2$. Indeed, one still has a central dip reaching zero at $t_D = 0$. However, by increasing the delay one observes the emergence of subdips for $q > 1$. It is worth noticing that the number of these sub-dips is equal to $2q-2$. Due to the presence of a unique edge channel, one cannot interpret this emerging structure in terms of the fractionalization discussed in the previous Sections. In contrast, this phenomenology can be explained in terms of a different process, namely a crystallization of Levitons carrying an integer charge q occurring in the time domain. This is a consequence of the fact that the injected wave-packet reorganizes into several sub-peaks at the output of the QPC due to the strong repulsion between the electrons composing it as show by the excess of particle density at the output of the QPC reported in Fig. 8 below.

Fig. 7 Ratio Q as a function of t_D/T for equal injected charge $q = 1$ (black curve), $q = 4$ (green curve), $q = 5$ (red curve) and $q = 6$ (blue curve). The free fermion case at $\nu = 1$ (dashed lines) is compared to the fractional case at $\nu = 1/3$ (solid lines). The other parameters are $\tau_0/T = 0.04$ and $\omega_c = 100\Omega$. Conclusion

This Chapter represents an overview of the subject of Electron Quantum Optics, with particular focus on the role played by electron-electron interaction in collisional interferometric experiments.

The analogies between conventional quantum optics experiments, based on the manipulation of individual photonic degrees of freedom, and their fermionic counterparts, involving electronic wave-packets ballistically propagating along mesoscopic channels realized in solid-state devices such as the edge states of the quantum Hall effect have been addressed.

The behavior of the electronic versions of Hanbury-Brown-Twiss and Hong-Ou-Mandel interferometers has been discussed in detail, underlying the fact that while the first provide information about the corpuscular nature of the excitations, the second can shed light on the interplay between Fermionic statistics and interaction effects. In particular, the role of statistics is encoded in the so called Pauli dip, a suppression of the current fluctuations associated to the anti-bunching of electrons that reach a quantum point contact at the same time.

To describe the effects of interaction, we have introduced the Luttinger liquid picture, universally accepted as the proper way to treat interacting systems confined in one spatial dimension, where the conventional Fermi liquid paradigm fails. To better address experimentally relevant situations, we have focused on the case of a quantum Hall state at filling factor $\nu = 2$, where two capacitively coupled edge channels co-propagate at the edge of the Hall bar. Here, a fractionalization of the injected voltage pulses occurs. At the level of collisional Hong-Ou-Mandel experiments this phenomenology leads to a deformation of the Pauli dip with the emerge of side dips.

Even more dramatic departures from the single Pauli dip profile, typical of the free fermion picture, can be observed in strongly interacting electron systems such as the fractional quantum Hall edge channels. Here, collisional experiments are characterized by the emergence of a number of side dips which grows with the charge carried by the injected pulses. This can be interpreted as a crystallization in the time domain, namely a rearrangement of the profile of a wave-packet carrying multiple electrons, as a consequence of the intense Coulomb interaction.

Abstract

In this article, we review the main theoretical methods applied to the study of liquid Helium adopting a microscopic approach, that is, starting from the many-particle Hamiltonian of the system. Following an introduction on the first early approaches, we discuss two main issues. In the first one, we report the main ingredients of a theoretical approach based on the variational method, with the discussion of the high accuracy obtained with them and the related progress in the design of highly accurate trial wave functions. In the second part, the main stochastic methods used in this study are briefly discussed. Altogether reflects the strong links between the study of liquid Helium and the progress in the development of new and extremely powerful approaches to deal with one of the most strongly quantum many-body systems in Nature.

Key points

- Main physical properties of liquid Helium, both in its superfluid and normal states
- Early phenomenological theoretical approaches to account for the main experimental data
- Development of theoretical approaches from a microscopic view: variational and correlated basis function theories
- Theoretical study based on stochastic methods: quantum Monte Carlo

Introduction

Liquid Helium was first liquefied by Kammerlingh Onnes in 1908 ([Kammerlingh Onnes, 1908](#)) and, since then, it has been one of the most studied quantum systems. Two of its isotopes are stable, ^4He and ^3He . In naturally produced Helium, the fraction of ^3He is extremely small, 1 part in 10^6 , and is produced from radioactive decay of tritium. Both isotopes remain in liquid state even in the limit of zero temperature, manifesting in this way their intrinsic quantum nature. Contrarily to classical theory, that predicts that any material becomes solid in that limit, quantum mechanics explain this fail of the classical approach by considering the zero-point kinetic energy. The combination of the light mass of Helium atoms and their weak attraction produces the unique opportunity of observing the most paradigmatic quantum liquid. ^4He and ^3He have different masses but the most crucial difference between both isotopes affects their behavior as quantum many-body systems: ^4He is composed by an even number of spin $1/2$ particles and thus, it is a boson, whereas ^3He has an odd number of constituents and behaves as a fermion. As we will discuss in this article, the different quantum statistics of the two Helium isotopes produces dramatic differences between them.

In ^4He , the specific heat shows a large excess at a temperature of 2.17 K, signaling the emergence of a phase transition, first observed by [Keesom and Clusius \(1932\)](#). The specific heat shows a shape similar to the λ Greek letter and is now universally known as the λ phase transition, with a critical temperature $T_c = 2.17$ K. This second-order transition separates two liquids with different properties and were termed liquid He I and liquid He II for $T > T_c$ and $T < T_c$, respectively. In 1938, P. Kapitza ([Kapitza, 1938](#)), from one side, and [Allen and Misener \(1938\)](#), on the other, published back-to-back papers announcing the discovery of superfluid ^4He in the Helium II phase. For an insightful historical analysis of the role played by the two independent teams on that discovery, we recommend the paper by [Balibar \(2007\)](#). Below T_λ , ^4He flows with vanishingly small viscosity producing a set of surprising effects such as the fountain effect, absence of boiling due to the large thermal conductivity, and second sound ([Wilks, 1967](#)).

Early approaches

In the early theoretical approaches to understand the extraordinary behavior of liquid Helium around the λ point, four names appear above many others: Laszlo Tisza, Lev Landau, Fritz London, and Nikolai Bogoliubov. Tisza and Landau worked in a

quantum hydrodynamic approach with the main idea of Helium as a liquid composed by two independent liquids (velocity fields). This is the basis of the two-fluid model first introduced by Tisza (1938) and then completed by Landau (1941). The two-fluid model assumes that the total density is the sum of two partial densities: the normal and the superfluid. Below T_λ , the superfluid component dominates, thus explaining the superfluid properties of Helium II. Increasing the temperature, at $T \geq T_\lambda$, the superfluid density turns to be zero and the total density equals the normal one.

Landau (1941) introduced the concept of quasiparticle to postulate the shape of the excitation spectrum. Instead of single-particle excitations, the system presents collective modes that at low momenta are termed phonons, in resemblance with the excitation spectrum of a crystal. At low momenta, the excitations are linear with the momenta, the slope being the speed of sound. At larger momenta, Landau defined another type of collective excitations which were named rotons, since where initially related to the presence of quantized vortices. Landau predicted that below a certain velocity, termed critical velocity, the system cannot be excited and thus liquid Helium flows without friction. Combining phonons and rotons, Landau (1947) was able to draw the excitation spectrum of Helium before any measure of it was made.

The hydrodynamic theory by Tisza and Landau did not take into account the quantum statistics of ^4He because they believed that this feature was not relevant to understand the superfluidity and the λ phase transition. On the contrary, London (1938) argued that a Bose gas experiences a second-order phase transition that can explain, at least qualitatively, the λ transition in ^4He . Applying the critical temperature derived in the Bose-Einstein statistics,

$$k_B T_{\text{BEC}} = \frac{2\pi\hbar^2}{m} \left(\frac{n}{g_{3/2}(1)} \right)^{2/3}, \quad (1)$$

with $g_{3/2}(1) \simeq 2.612$ and n the density, to the case of Helium London obtained 3.1 K, not so far from T_λ . Landau always ignored London approach to the problem (Balibar, 2007) because with his hydrodynamic theory he was able to account for many experimental facts. However, we know now that the quantum statistics of ^4He is crucial to understand superfluid ^4He . When samples of ^3He were produced, we learned that ^3He , which is a fermion, do not show the λ phase transition.

Bogoliubov, in 1947 (Bogoliubov, 1947), was the first to connect the elementary excitation spectrum with a Bose-Einstein gas with repulsive but small interatomic interaction. He proved that the lowest energy excitations are collective modes (phonons) that at low momenta are proportional to the speed of the sound, in agreement with Landau theory. The Bogoliubov excitation spectrum (Pitaevskii and Stringari, 2016)

$$\varepsilon(p) = \left[\frac{gn}{m} p^2 + \left(\frac{p^2}{2m} \right)^2 \right]^{1/2}, \quad (2)$$

with g as the interaction strength predicts a critical velocity which is always equal to the speed of sound. Bogoliubov theory was again qualitatively correct but Helium is not a rarefied gas but a liquid with strong interparticle interactions.

Microscopic theories

We discuss first liquid ^4He . ^3He was obtained later in time due to its complex experimental production. As we commented in the previous section, Bogoliubov (1947) introduced field theoretical models in the theoretical description of liquid ^4He , but his approach was only applicable to dilute Bose gases, and this is far from the real properties of Helium. This is specially evident from the explicit assumption in Bogoliubov analysis that all the particles of the system are in the Bose-Einstein condensate, whereas in ^4He only 7% of them are really in this state due to the unavoidable role played by atomic correlations. In subsequent work, Beliaev (1958) introduced Green functions $G_{\alpha,\beta}(q, \omega)$ in the formalism, deriving a general equation for them at zero temperature. The quantum field theory for a Bose fluid was reanalyzed by Hugenholtz and Pines (1959) by the introduction of the chemical potential μ to guarantee the number conservation of the theory. Importantly, they removed the constraint of a full condensate, approaching better the characteristics of liquid Helium. An important result of this approach was the calculation of the energy of a Bose gas incorporating the first corrections to the Hartree-Fock energy

$$\frac{E}{N} = 4\pi na^3 \left[1 + \frac{128}{15\sqrt{\pi}} \sqrt{na^3} + \frac{8(4\pi - 3\sqrt{3})}{3} na^3 \ln(na^3) + \dots \right], \quad (3)$$

the energy per particle E/N being in units of $\hbar^2/(2ma^2)$. Hugenholtz and Pines (1959) proved that, beyond the expansion terms in Eq. (3), additional contributions will depend on the specific shape of the interatomic potential and not only on the s -wave scattering length a . The coefficient of the $(na^3)^{3/2}$ term was first calculated by Lee et al. (1957), while the coefficient of the last term was first obtained by Wu (1959). Both of them were originally derived for hard spheres, but it was shown that the same expansion is valid for any repulsive potential with scattering length a (Hugenholtz and Pines, 1959). Eq. (3) has been very useful in the study of dilute Bose gases, composed by alkali atoms, due to their extreme diluteness (Pitaevskii and Stringari, 2016). However, liquid Helium is a strongly interacting quantum many-body system in which any expansion in terms of the gas parameter na^3 is completely useless.

The first theoretical approach based on the wave function of the N -body quantum system was made by Feynman (1953). This work opened a new way to deal with the properties of Helium based on a microscopic approach. Starting from general arguments,

that included the symmetry of the ^4He atoms and their hard-core interactions at short distances, Feynman argued that the lowest energy excitations have a collective behavior since single-particle ones have always higher energy. Based on these considerations, he wrote the wave function of the excited state of the N -body fluid as

$$\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) = \prod_{i=1}^N f(\mathbf{r}_i) \Phi(\mathbf{r}_1, \dots, \mathbf{r}_N), \quad (4)$$

where $\Phi(\mathbf{r}_1, \dots, \mathbf{r}_N)$ is the ground-state wave function. Eq. (4) is a variational approach to the problem and thus the energy of the excitation is an upper bound to the exact energy. He obtained the lowest excitation energy

$$\hbar\omega_F(q) = \frac{\hbar^2 q^2 / 2m}{S(q)}, \quad (5)$$

where $S(q) = 1/N \langle \rho^\dagger(q) \rho(q) \rangle$ is the static structure factor, and $\rho(q) = \sum_i \exp(-iq \cdot \mathbf{r}_i)$ is the density fluctuation operator. When $q \rightarrow 0$, $S(q) = \hbar q / (2mc)$, where c is the speed of sound. In this way, Feynman recovers the phonon relation previously found by Landau and Bogoliubov, $\hbar\omega = cq$, that is, a linear behavior. At large momenta, the static structure factor tends to 1 and so one recovers the excitation energy of a free particle $\hbar^2 q^2 / 2m$, quadratic with q . At intermediate q values, $S(q)$ shows a peak related to the mean interparticle distance and thus the excitation energy (5) shows a local minimum that we can identify with the roton. Qualitatively, the Feynman spectrum is correct up to momenta not much larger than the one of the roton but the roton energy is nearly two times larger than the experimental one. The minimum energy (5) is obtained with a function $f(r) = \exp(iq \cdot \mathbf{r})$, so the total wave function (4) is given by

$$\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) = \prod_{i=1}^N e^{iq \cdot \mathbf{r}_i} \Phi(\mathbf{r}_1, \dots, \mathbf{r}_N) = \rho^\dagger(q) \Phi(\mathbf{r}_1, \dots, \mathbf{r}_N), \quad (6)$$

that emerges as the creation of a collective mode of momentum q acting on the ground-state, that is not changed by the excitation.

Feynman and Cohen (1956) improved the initial theory by introducing in the wave function two-body correlations. Their idea is that when one particle moves in the fluid its neighbors *feel* the movement or, in other words, the movement of each particle depends on its local environment. They termed these correlations as backflow correlations. Explicitly, the wave function of the collective excitation turns to

$$\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) = \prod_{i=1}^N \left[e^{iq \cdot \mathbf{r}_i} \sum_{j \neq i} e^{ig(\mathbf{r}_i - \mathbf{r}_j)} \right] \Phi(\mathbf{r}_1, \dots, \mathbf{r}_N). \quad (7)$$

The function $g(r)$ in Eq. (7) couples the movement of the excited particle i with the neighboring ones. In Feynman and Cohen (1956), it is taken as a dipolar term, $g(r) = \alpha q \cdot \mathbf{r} / r^3$ and the imaginary exponential containing $g(r)$ is linearized to make the calculation of the energy simpler. With this correction, the difference between the Feynman roton energy (5) and the experimental one is reduced to a factor of ~ 2 but still there is a significant difference.

To reproduce as better as possible the elementary excitation spectrum of liquid ^4He is not the only goal of a microscopic theory. It is fundamental to have an accurate description of the ground state of the system. The most fruitful approach to account for the equation of state of liquid ^4He has been the variational theory since standard perturbative approaches are not applicable due to the hard core of the He–He interaction at short distances. The Hamiltonian of the N -particle system is

$$H = -\frac{\hbar^2}{2m} \sum_{i=1}^N \nabla_i^2 + \sum_{i < j} V(r_{ij}), \quad (8)$$

where $V(r)$ is the pair interatomic potential. One can add to Eq. (8) three-body potentials, whose analytic form is not well known. However, its contribution to the energy seems to be not relevant and the results can even worsen (Boronat and Casulleras, 1994). In the description of the bulk phases, one always assumes the thermodynamic limit: $N \rightarrow \infty$, $\Omega \rightarrow \infty$, and the density $\rho = N/\Omega$ is finite. For a trial wave function Ψ , not orthogonal to the ground state, the Ritz's variational principle of quantum mechanics states that

$$E = \frac{\langle \Psi | H | \Psi \rangle}{\langle \Psi | \Psi \rangle} \geq E_0, \quad (9)$$

where E_0 is the ground-state energy of the system. The wave function Ψ must be symmetric under the interchange of particles and approaches zero when $r_{ij} \rightarrow 0$. Also, when a set of particles is significantly far way from the rest of the system, the total wave function factorizes, that is, the cluster property is fulfilled. The first model wave function that comes to mind is a symmetrized product of single-particle wave functions which, for a bulk phase, are plane waves. However, this model clearly violates both crucial properties. Bijl (1940) and Jastrow (1955) proposed a model to account with the restrictions imposed by a strongly correlated fluid,

$$\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) = \prod_{i=1}^N g(r_i) \prod_{i<j}^N f(r_{ij}), \quad (10)$$

where $f(r)$ is a two-body correlation factor and $g(r)$ is a one-body function that, in the bulk phase, is simply 1 (ground state). The function $f(r)$ plays an essential role in the study of Helium and satisfies two main properties: it becomes zero, approaching the hard core of the potential, and one at large distance, according to the cluster property. In Fig. 1, we show the characteristic shape of the potential and the two-body correlation factor.

The energy per particle for a Bijl–Jastrow wave function is readily obtained as

$$\frac{E}{N} = \frac{1}{2} \rho \int d\mathbf{r} \left[V(r) - \frac{\hbar^2}{2m} \nabla^2 \ln f(r) \right], \quad (11)$$

with $g(r)$ the two-body radial distribution function

$$g(r_{12}) = \frac{N(N-1)}{\rho^2} \frac{\int d\mathbf{r}_3 \dots d\mathbf{r}_N |\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N)|^2}{\int d\mathbf{r}_1 \dots d\mathbf{r}_N |\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N)|^2}, \quad (12)$$

which is proportional to the probability of finding two particles at distance r . Accessing to the function $g(r)$ allows for the calculation of the energy of the system and further properties. However, as Eq. (12) shows, its estimation is very difficult due to the multidimensional integrals that need to be carried out. A fruitful approach in the study of liquid Helium has been the hypernetted chain theory (HNC) based on the summation of the series in terms of the function $h(r) = f^2(r) - 1$ in which $g(r)$ can be expressed. This function $h(r)$ is different from zero only at short distances and allows for a cluster expansion. $g(r)$ is given exactly by

$$g(r) = f^2(r) \exp(N(r) + E(r)), \quad (13)$$

where $N(r)$ and $E(r)$ are functions summing up specific terms of the series, known as nodal and elementary diagrams, respectively. Nodal diagrams can be calculated by solving the HNC integral equation

$$N(r_{12}) = \rho \int d\mathbf{r}_3 [g(r_{13}) - 1][g(r_{32}) - N(r_{32}) - 1]. \quad (14)$$

On the contrary, elementary diagrams cannot be summed up and, thus, only approximated in some way (Usmani et al., 1982b; Fabrocini and Rosati, 1982; Clements et al., 1993). Therefore, Eq. (13) cannot be evaluated in an exact and closed form using this theory.

The variational upper bound to the exact energy depends on the trial wave function. One can guess an analytic model for it, with a set of variational parameters to be optimized. Otherwise, one can approach the optimization via a functional derivative, normally written in terms of the two-body distribution function $g(r)$,

Fig. 1 He–He interatomic potential $V(r)$ and the two-body correlation factor $f(r)$.

$$\frac{\delta E[g(r)]}{\delta g(r)} = 0, \quad (15)$$

where $E[g(r)]$ is the energy of the system. This can be written only in terms of $g(r)$ by using Eq. (13),

$$E[g(r)] = \frac{\rho}{2} \int dr g(r) V(r) + \frac{\hbar^2 \rho}{2m} \int dr \left[\left(\nabla \sqrt{g(r)} \right)^2 + \frac{1}{4} g(r) \nabla^2 E(r) \right] - \frac{\hbar^2}{8m} \frac{1}{2\pi^3 \rho} \int dk k^2 \frac{(S(k) - 1)^3}{S(k)}. \quad (16)$$

Imposing the minimization condition (15), one arrives to the Euler–Lagrange differential equation for the optimal correlation (Lantto et al., 1977; Kallio and Smith, 1977)

$$-\frac{\hbar^2}{m} \nabla^2 \sqrt{g(r)} + (V(r) + W(r)) \sqrt{g(r)} = 0. \quad (17)$$

This equation needs to be solved iteratively (Jackson et al., 1979) because the potential $W(r)$ depends on the correlation function. Neglecting the contribution of the elementary diagrams, this induced potential is better written in reciprocal space as

$$\tilde{W}(q) = -\frac{\hbar^2 q^2 (S(q) - 1)(2S(q) + 1)}{4m S(q)^2}, \quad (18)$$

where $S(q)$ is the static structure factor,

$$S(q) = \frac{1}{N} \langle \rho_q \rho_{-q} \rangle = 1 + \rho \int dr e^{iq \cdot r} (g(r) - 1). \quad (19)$$

At zero temperature, the function $S(q)$ satisfies $S(0) = 0$ and shows the phononic behavior at small q

$$\lim_{q \rightarrow 0} S(q) = \frac{\hbar q}{2mc}, \quad (20)$$

where c is the speed of the sound. This behavior at small q produces a long-range behavior of the two-body correlation factor (Feenberg, 1969)

$$\lim_{r \rightarrow \infty} f(r) = 1 - \frac{mc}{2\pi^2 \hbar \rho r^2}. \quad (21)$$

Remarkably, the optimal $f(r)$ obtained from the Euler–Lagrange Eq. (17) satisfies the phonon behavior (21) (Castillejo et al., 1979), even if the speed of sound that derives from that differs from the experimental one.

At zero temperature, the superfluid fraction of ^4He is one but the occupation of the zero-momentum state, that is the Bose–Einstein condensate, is significantly smaller than one due to the relevance of correlations. Microscopically, the condensate fraction n_0 , and the momentum distribution in general, can be calculated through the one-body density matrix

$$\rho(r_{11'}) = \Omega \frac{\int dr_2 \dots dr_N \Psi(r_1, \dots, r_N) \Psi(r_1', \dots, r_N)}{\int dr_1 \dots dr_N |\Psi(r_1, \dots, r_N)|^2}, \quad (22)$$

normalized as $\rho(0) = 1$. Fourier transforming $\rho(r)$ one gets the momentum distribution

$$n(q) = n_0 \delta(q) + \rho \int dr (\rho(r) - n_0) e^{iq \cdot r}, \quad (23)$$

where $n_0 = \lim_{r \rightarrow \infty} \rho(r)$ is the condensate fraction. The momentum distribution (23) can be measured using deep inelastic neutron scattering at large momentum transfer. The condensate fraction is quite small $n_0 \sim 0.07$ and its estimation, from the dynamic structure factor $S(q, \omega)$, requires from an accurate analysis of final state effects (Glyde, 1994). A variational estimation of the one-body density matrix and the condensate fraction can be made using a HNC cluster expansion similar to the one developed for $g(r)$ (Fantoni, 1978).

With the best Jastrow factor, the upper bound to the energy provided by the variational calculation is still 15% above the exact quantum Monte Carlo results (see next section) for the same interatomic potential and at densities close to the equilibrium point. An important advance on the improvement of the variational energy was the introduction of three-body correlations in the trial wave function,

$$\Psi_{\Gamma}(r_1, \dots, r_N) = \prod_{i < j} f(r_{ij}) \prod_{i < j < k} f_3(r_{ij}, r_{ik}, r_{jk}), \quad (24)$$

which corrects the description of correlation effects at short and medium interparticle distances. The relevance of these correlations in the study of liquid Helium derives from its relatively large density, which drives this liquid into the realm of one of the most correlated quantum systems in Nature. The origin of the function f_3 , and its specific functional form, can be derived in different

ways: introducing a momentum dependence in the two-body correlation factor (Pandharipande, 1978) or by searching the first correction to the Jastrow factor by linearizing the imaginary-time Schrödinger equation (Boronat, 2002). It adopts the form

$$f_3(r_{ij}, r_{ik}, r_{jk}) = \exp\left(-\frac{1}{2} q(r_{ij}, r_{ik}, r_{jk})\right), \quad (25)$$

where

$$q(r_{ij}, r_{ik}, r_{jk}) = \sum_l \sum_{\text{cyc}} \xi_l(r_{ij}) \xi_l(r_{ik}) P_l(\hat{r}_{ij} \cdot \hat{r}_{ik}), \quad (26)$$

where l is the angular momentum and P_l the Legendre polynomial. The most important, and most used contribution, corresponds to $l = 1$. The pair function $\xi(r)$ in Eq. (26) is assumed to be a short-range correlation factor

$$\xi(r) = \sqrt{\lambda} \exp\left[-\left(\frac{r - r_v}{r_\omega}\right)^2\right], \quad (27)$$

where λ , r_v and r_ω variational parameters to be optimized. The HNC equations can be generalized to allow for the inclusion of three-body correlations in the diagrammatic expansions (Usmani et al., 1982a). The energies obtained so far reduce in a $\sim 70\%$ the difference between the Jastrow upper bound and the exact values, pointing to its importance for a right microscopic description of liquid ^4He .

The theoretical description of liquid Helium is not complete without understanding the dynamics of the system (Godfrin and Krotscheck, 2022). The dynamic structure function $S(q, \hbar\omega)$ contains the maximum information about it and is experimentally accessible by inelastic scattering through

$$\frac{\partial^2 \sigma}{\partial \Omega \partial \hbar\omega} = b^2 \left(\frac{q_1}{q_0}\right) S(q, \hbar\omega), \quad (28)$$

with the left part being the double differential cross section. In Eq. (28), b is the scattering length of the nucleus, and q_0 and q_1 are the initial and final momentum of the neutron. The momentum and energy transferred to the liquid are $q = q_1 - q_0$ and $\hbar\omega$, respectively. At zero temperature, and for a N particle system,

$$S(q, \hbar\omega) = \frac{1}{N} \sum_n |\langle \Psi_n | \rho(q) | \Psi_0 \rangle|^2 \delta(\hbar\omega - (E_n - E_0)), \quad (29)$$

where the sum is extended to all the excited states and $\rho(q)$ is the density fluctuation operator. To calculate the dynamic response one invokes linear response theory, where the change in the density under the action of an external tiny time-dependent potential is

$$\delta\rho(r, t) = \int dr' dt' \chi(r, r', t - t') \delta V_{\text{ext}}(r', t'), \quad (30)$$

where χ is the density–density response function. The dynamic response can be obtained from the imaginary part of the Fourier transform of χ ,

$$S(q, \hbar\omega) = -\frac{1}{N\pi} \Im \left[\int dr dr' e^{iq \cdot (r - r')} \chi(r, r', \hbar\omega) \right], \quad (31)$$

and the evolution in time of $\delta\rho(r, t)$ from the least-action principle $\delta S = 0$. The calculation of the dynamic response of liquid Helium has been the object of intense work for many years. Regular perturbation theory does not work because of the hard core of the He–He interaction and then it is necessary to work out the theory using correlated basis functions (CBFs). From pioneering work by Jackson and Feenberg (1962) and Lee and Lee (1975), the major progress has been achieved by dynamic many-body theory developed by Campbell and Krotscheck (2009) and Campbell et al. (2015). Recently, a comparison between very accurate experimental data, on the dynamic response and the excitation spectrum, and theoretical results obtained with dynamic many-body theory has shown an impressive agreement (Beauvois et al., 2018).

Until here, we have focused our discussion on the studies of bosonic liquid ^4He . But, Helium offers another stable isotope, ^3He , which is a fermion. At very low temperatures, it remains in a liquid state that becomes superfluid at ~ 2 mK. In the following, we refer to normal nonsuperfluid ^3He since superfluid ^3He is a very different subject which would require a completely different scope. The variational wave function incorporates the Fermi statistics in the well-known Jastrow–Slater form

$$\Psi(r_1, \dots, r_N) = \prod_{i < j}^N f(r_{ij}) \Phi(r_1, \dots, r_N), \quad (32)$$

where Φ is an antisymmetric wave function, usually taken as the product of Slater determinants $\Phi = D_\uparrow D_\downarrow$ since the interaction is spin independent. Variational theory, based on cluster expansion and summation of proper diagrams, to calculate the pair distribution function $g(r)$ is now more involved than in Bose fluids. The extension of HNC theory is known as Fermi-hypernetted chain (FHNC), and the convergence of the series summation was proved in the seventies of the past century (Fantoni and Rosati, 1975;

Krotscheck and Ristig, 1975). This theory was reviewed in depth by Rosati (1981) and a modern update was carried out by Krotscheck (2000). As in the case of ^4He , the inclusion in the trial wave function (32) of triplet correlations reduces significantly the difference with quantum Monte Carlo estimations. Even with the introduction of three body factors into the variational model, the Jastrow–Slater model uses Slater determinants with free single-particle orbitals. A relevant improvement of the variational model is achieved by modifying these orbitals to include, in an approximate way, the effect of correlations on them. This is usually made with backflow correlations, where the orbitals are $\exp(i\mathbf{k}\cdot\tilde{\mathbf{r}}_i)$, with

$$\tilde{\mathbf{r}}_i = \mathbf{r}_i + \lambda \sum_{j \neq i} \eta(r_{ij}) \mathbf{r}_{ij}, \quad (33)$$

where $\eta(r)$ is a short-ranged function as a Gaussian (Manousakis et al., 1983). The calculation of excited states of ^3He has also been possible by using CBF theory with increasing complexity due to Fermi statistics (Fabrocini and Rosati, 1988). The high accuracy of CBF theory has been recently proved in a comparison between its predictions and very accurate experimental data on films of ^3He (Godfrin et al., 2012).

Working with the two isotopes of Helium, it is also possible to have stable mixtures of ^3He and ^4He , that is a Fermi–Bose mixture. In the limit of zero temperature, the mixture is stable up to a maximum ^3He concentration of 6.5% (Ebner and Edwards, 1970). This isotopic mixture was first studied neglecting the Fermi character of ^3He atoms showing that the isotopic Bose–Bose mixture is not stable at any finite concentration (Chakraborty, 1982). To get realistic results and finite solubilities, it is mandatory to consider ^3He atoms as fermions. The HNC/FHNC equations were generalized to the mixture by Fabrocini and Polls (1982) and then extended to study the momentum distribution of the mixture (Boronat et al., 1997). The limiting case of a single impurity, known also as polaron, was also studied using HNC/CBF formalism both for the ^3He impurity in bulk ^4He (Boronat et al., 1989) (Bose polaron) and for the ^4He impurity in ^3He (Arias de Saavedra et al., 1994) (Fermi polaron).

Quantum Monte Carlo methods

Variational methods discussed in the previous section have been tremendously effective in the description of liquid Helium, with special significance on the accuracy achieved in the calculations of the dynamic response. However, the application of the variational principle guarantees upper bounds to the ground-state energies and it is difficult to know what remains between the bounds and exact values. Quantum Monte Carlo methods exploit the power of stochastic simulations to go beyond the bounds of the variational theories and obtain exact estimations within some statistical noise.

We first discuss the $T = 0$ ground state with projection methods. The two methods that have been used in the study of liquid ^4He are Green’s function Monte Carlo (GFMC) and diffusion Monte Carlo (DMC). GFMC is the most accurate method because it has not any time-step dependence but its implementation is involved. Instead, DMC is a simpler method but with time-step dependence. Nowadays, DMC has become the most used tool.

The DMC method solves the Schrödinger equation, written in imaginary time,

$$-\frac{\partial \Psi(\mathbf{R}, t)}{\partial t} = (H - E) \Psi(\mathbf{R}, t), \quad (34)$$

where $\mathbf{R} \equiv (\mathbf{r}_1, \dots, \mathbf{r}_N)$ is a $3N$ -dimensional vector (walker) and t is the imaginary time. As it is usual in quantum mechanics, the time-dependent wave function of the system $\Psi(\mathbf{R}, t)$ can be expanded in terms of a complete set of eigenfunctions $\phi_i(\mathbf{R})$ of the Hamiltonian

$$\Psi(\mathbf{R}, t) = \sum_n c_n \exp[-(E_i - E)t] \phi_i(\mathbf{R}), \quad (35)$$

where E_i is the eigenvalue associated to $\phi_i(\mathbf{R})$. The asymptotic solution of Eq. (34) for any value E close to the energy of the ground state, and for long times ($t \rightarrow \infty$), gives $\phi_0(\mathbf{R})$, provided that there is a nonzero overlap between $\Psi(\mathbf{R}, t = 0)$ and the ground-state wave function $\phi_0(\mathbf{R})$.

A direct Monte Carlo implementation of Eq. (34) is hardly able to work efficiently, especially in liquid Helium where the interatomic potential contains a hard core. To reduce the variance, one uses importance sampling, consisting in rewriting the Schrödinger equation in terms of the wave function

$$f(\mathbf{R}, t) \equiv \psi(\mathbf{R}) \Psi(\mathbf{R}, t), \quad (36)$$

where $\psi(\mathbf{R})$ is a time-independent trial wave function that describes approximately the ground state of the system at the variational level. Then, Eq. (34) turns out to be

$$-\frac{\partial f(\mathbf{R}, t)}{\partial t} = -D \nabla_{\mathbf{R}}^2 f(\mathbf{R}, t) + D \nabla_{\mathbf{R}}(F(\mathbf{R}) f(\mathbf{R}, t)) + (E_L(\mathbf{R}) - E) f(\mathbf{R}, t), \quad (37)$$

where $D = \hbar^2/(2m)$, $E_L(\mathbf{R}) = \psi(\mathbf{R})^{-1} H \psi(\mathbf{R})$ is the local energy, and

$$F(\mathbf{R}) = 2 \psi(\mathbf{R})^{-1} \nabla_{\mathbf{R}} \psi(\mathbf{R}) \quad (38)$$

is called drift or quantum force. $F(\mathbf{R})$ acts as an external force which guides the diffusion process, involved by the first term in Eq. (37), to regions where $\psi(\mathbf{R})$ is large.

The r.h.s. of Eq. (37) may be written as the action of three operators A_i acting on the wave function $f(\mathbf{R}, t)$

$$-\frac{\partial f(\mathbf{R}, t)}{\partial t} = (A_1 + A_2 + A_3) f(\mathbf{R}, t) \equiv A f(\mathbf{R}, t). \quad (39)$$

The Schrödinger Eq. (39) is written in an integral form by introducing the Green function $G(\mathbf{R}', \mathbf{R}, t)$, which gives the transition probability from an initial state $\mathbf{R}$ to a final one $\mathbf{R}'$ during a time t

$$f(\mathbf{R}', t + \Delta t) = \int G(\mathbf{R}', \mathbf{R}, \Delta t) f(\mathbf{R}, t) d\mathbf{R}. \quad (40)$$

The DMC method relies on reasonable approximations of $G(\mathbf{R}', \mathbf{R}, \Delta t)$ for small values of the time-step Δt . Considering such a short-time approximation, Eq. (40) is then iterated repeatedly until to reach the asymptotic regime $f(\mathbf{R}, t \rightarrow \infty)$, a limit in which one is effectively sampling the ground state.

As it is shown in Fig. 2, the accuracy achieved by the DMC method to reproduce the experimental equation of state is impressive (Boronat and Casulleras, 1994). The dependence of the energy with the density is well reproduced, in spite of a nearly constant shift that it is related to the interatomic potential used in the simulations. We observe that the shift is practically constant looking at the dependence of the pressure with the density, as shown in Fig. 2.

Quantum Monte Carlo methods are able to estimate other properties than the energy. However, direct estimations of operators which do not commute with the Hamiltonian are biased by the trial wave function used for importance sampling. To eliminate this bias, it is necessary to work with pure estimators (Casulleras and Boronat, 1995), based on the forward-walking method (Liu et al., 1974). In Fig. 3, we show DMC results for the static structure factor $S(q)$, calculated with pure estimators, in comparison with experimental data obtained from X-rays (Wirth and Hallock, 1987) and neutron scattering (Svensson et al., 1980). As one can see, the agreement between theory and experiment is excellent.

The study of the Fermi isotope ^3He using Monte Carlo is much more involved due to the famous sign problem. In fact, the Monte Carlo interpretation of the imaginary-time Schrödinger equation requires that $f(\mathbf{R}, t) = \psi(\mathbf{R})\Psi(\mathbf{R}, t)$ be a density, that is, $\psi \Psi \geq 0$ in all the domain. This boundary condition can be satisfied if ψ and Ψ change sign together and thus share the same nodes. This approximation, known as fixed-node (FN) method, (Reynolds et al., 1982) has been extensively used in the ground-state calculations of Fermi quantum liquids. It can be proved that, due to that nodal constraint, the FN energies are variational upper bounds to the exact eigenvalues for a given symmetry (Reynolds et al., 1982). Therefore, the FN results depend significantly on the quality of the trial wave function. The best upper bounds have been achieved by introducing backflow correlations, which move the nodal surface according to the interparticle interactions. Recently, an iterative backflow scheme has shown accurate results for the ^3He equation of state (Taddei et al., 2015), in spite of being not so good as the ones obtained in ^4He , where the calculation is not affected by the sign problem.

The thermal properties of liquid ^4He have also been deeply studied using the path integral Monte Carlo (PIMC) method. As it is well known, the knowledge of the quantum partition function at finite temperature

Fig. 2 Left: Equation of state of liquid ^4He (Boronat and Casulleras, 1994): open and full circles are DMC results with the Aziz (Aziz et al., 1979) and Aziz II (Aziz et al., 1987) potentials, respectively; experimental values, solid triangles, from De Bruyn Ouboter and Yang (1987). Right: Pressure as a function of density of liquid ^4He : points, experimental results (De Bruyn Ouboter and Yang, 1987), and solid line, DMC results.

Fig. 3 DMC static structure function (points) for liquid ${}^4\text{He}$ at ρ_0^{expt} , in comparison with experimental determinations from Svensson et al. (1980) (solid line) and Wirth and Hallock (1987) (dashed line). The error bars of the theoretical points are only shown where larger than the size of the symbols.

$$Z = \text{Tr } e^{-\beta \hat{H}} \quad (41)$$

allows for a full microscopic description of the properties of a given system, where $\beta = 1/T$ and $\hat{H} = \hat{K} + \hat{V}$ is the Hamiltonian. The noncommutativity of the quantum operators, kinetic $\hat{K}$ and potential $\hat{V}$ energies, makes impractical a direct calculation of the partition function Z (41). Instead, all practical implementations intended for Monte Carlo estimations of Z rely on approximations that use as a starting point the convolution property

$$e^{-\beta(\hat{K}+\hat{V})} = \left(e^{-\varepsilon(\hat{K}+\hat{V})} \right)^M, \quad (42)$$

with $\varepsilon = \beta/M$, where each one of the terms in the r.h.s. corresponds to a higher temperature MT . In the most simple approximation, known as primitive action (PA), the kinetic and potential contributions factorize

$$e^{-\varepsilon(\hat{K}+\hat{V})} \simeq e^{-\varepsilon\hat{K}} e^{-\varepsilon\hat{V}}, \quad (43)$$

the convergence to the exact result being warranted by the Trotter formula (Trotter, 1959)

$$e^{-\beta(\hat{K}+\hat{V})} = \lim_{M \rightarrow \infty} \left(e^{-\varepsilon\hat{K}} e^{-\varepsilon\hat{V}} \right)^M. \quad (44)$$

The PA is a particular case of a more general expansion in which one can decompose the action, that is

$$e^{-\varepsilon(\hat{K}+\hat{V})} \simeq \prod_{i=1}^n e^{-t_i \varepsilon \hat{K}} e^{-v_i \varepsilon \hat{V}}, \quad (45)$$

where $\{t_i, v_i\}$ are parameters to be determined. A particular implementation of this expansion put forward by Chin (2004) has proved to be a full fourth-order approximation that even can behave as sixth order by tuning properly its free parameters (Sakkos et al., 2009). Alternatively, one can use the pair-action approximation, in which the total action is built as product of pair actions that are obtained either exactly or with some approximations (Ceperley, 1995). Considering distinguishable particles, the quantum partition function Z (41) can be obtained through a multidimensional integral of the M terms (beads) in which it is decomposed,

$$Z = \int d\mathbf{R}_1 \dots d\mathbf{R}_M \prod_{\alpha=1}^M \rho(\mathbf{R}_\alpha, \mathbf{R}_{\alpha+1}), \quad (46)$$

with $\mathbf{R} \equiv \{\mathbf{r}_1, \dots, \mathbf{r}_N\}$ and $\mathbf{R}_{M+1} = \mathbf{R}_1$. The PIMC method is then mapped to classical closed polymers composed by beads harmonically coupled by the kinetic action (Fig. 4).

To ensure the Bose symmetry of ${}^4\text{He}$, it is necessary to symmetrize the quantum partition function (41). This requires an additional sampling in the permutation space. The first applications of PIMC to liquid ${}^4\text{He}$ were made by proposing permutations between pairs, triplets, and more particles (Ceperley, 1995). However, this method becomes inefficient when the total number of particles in the simulation increases. A significant better performance has been achieved with the introduction of the worm algorithm, first proposed in lattice systems (Prokof'ev et al., 1998), and then extended to continuum fluids (Boninsegni et al., 2006).

Fig. 4 Schematic representation of two particles in the PIMC formalism. The springs stand for the harmonic coupling between beads of every single atom (kinetic action) and the *dashed lines* for the interatomic potential between beads of different atoms.

Fig. 5 Specific heat of liquid ^4He obtained with the PIMC method around the normal-to-superfluid λ phase transition. The line corresponds to experimental results (Wilks, 1967).

One of the more impressive successes of PIMC was the characterization of the normal-to-superfluid λ phase transition at a critical temperature $T_\lambda = 2.17$ K. In Fig. 5, we compare PIMC results of the specific heat as a function of T with experimental data. The estimation of the specific heat is numerically involved but its singularity at T_λ is well reproduced.

Conclusion

We have reported in this article some of the main theoretical approaches used in the study of liquid Helium. After an introduction on the physical properties of liquid Helium, we have discussed the early theoretical approaches used in its study. In Section “Microscopic theories,” we have discussed on the application of the variational theory and CBF as a best approach for its microscopic understanding. In Section “Quantum Monte Carlo methods,” we have introduced the main quantum Monte Carlo methods used in the study of liquid Helium.

This subject has been running for many years and it is impossible in practice to include all the immense work developed. Liquid Helium has been a continuous benchmark for quantum many-body theories and has been the workhorse for improving theories at all levels. This continued effort has produced a set of very accurate theoretical tools which have dramatically reproduced many experimental data. Liquid Helium is a really very strongly correlated quantum fluid where any simple perturbative scheme cannot be used. Remarkably, variational theory has proved to be the most efficient tool to deal with its microscopic description. Finally, it is also noticeable how progress in the development of quantum Monte Carlo methods has grown stimulated for the incredible amount of experimental data that we have at hands.

Abstract

We review experimental and theoretical progress in the physical description of the dynamics of the quantum fluids ⁴He and ³He. Historically, the elementary excitations in these systems have been identified as phonons and rotons and, in ³He, collective zerosound and spin-fluctuations. Both recent high-precision measurements and theoretical methods have shown that the dynamics of these systems is actually very rich as will be discussed in detail in the body of this contribution.

The helium liquids

Helium (⁴He and the less common isotope ³He) and hydrogen are simple condensed matter systems, amenable to fundamental quantum mechanical descriptions. Helium remains liquid even at the absolute zero of temperature, an effect explained by Heisenberg's uncertainty principle, which has the consequence that light atoms confined in a small volume have a large kinetic energy, as is the case in a liquid or a solid, where each atom is confined by several surrounding atoms. For this reason, in helium, kinetic energies are larger than the weak interatomic potential energy. Even at the lowest temperatures, substantial atomic motion is present, and the system remains liquid, unless pressures on the order of 25 MPa are applied, and solidification is achieved. Another quantum effect plays an important role in the behavior of liquid helium: as the temperature is reduced below a few degrees Kelvin, the thermal de Broglie wave-length of the atoms becomes larger than the interatomic distance. The waves describing the helium atoms overlap significantly, and a description in terms of individual wave-packets of distinguishable particles becomes inappropriate, it must be replaced by a quantum many-body description in terms of indistinguishable particles, governed by quantum statistics.

Quantum Mechanics and Statistical Physics (Fetter and Walecka, 1971; Thouless, 1972) explain well the properties of Quantum Gases, i.e., ensembles of non-interacting particles, which necessarily belong to one of the two possible classes: Bosons having an integer spin quantum number s , or fermions with half-integer spin. ⁴He atoms ($s = 0$) are bosons, and ³He atoms ($s = \frac{1}{2}$) are fermions.

The wave-functions of particles confined in a volume V are quantized plane waves characterized by their wave-vector $\mathbf{k}$. As shown by A. Einstein, the ground state of a Bose gas is the BEC (Bose Einstein condensate), where all particles occupy the same microscopic state with $\mathbf{k} = 0$. The ground state of a Fermi gas is very different, because Pauli's principle forbids double occupancy for Fermions: the particles form a Fermi sphere in wave-vector space, by completing successive energy levels of increasing wave-vector, up to the Fermi wave-vector k_F . The energy E_F of the last one, called the Fermi level, can be considerable.

The excitation spectrum $\varepsilon(k)$ of these quantum gases is simply given by the kinetic energies of the individual particles, $\varepsilon(k) = \hbar^2 k^2 / 2m$, where m is the particle mass and k the wave number. For bosons, at low temperatures, particles are excited from the common ground state. The energy spectrum is the usual parabolic spectrum of free particles described above. This behavior, however, is profoundly modified by interparticle interactions, i.e., as is the case in Quantum Fluids (Fetter and Walecka, 1971; Pines and Nozieres, 1966; Thouless, 1972; Wilks, 1967).

The Helium quantum fluids are unique in the sense that they are *very dense* and *very quantum*, making them a very challenging problem for theory. The issue is made quantitative by looking at the simple Lennard-Jones model of the helium fluids. In this model, the helium atoms interact via the interaction (Fig. 1)

$$V(r) = 4\varepsilon \left[\left(\frac{\sigma}{r} \right)^{12} - \left(\frac{\sigma}{r} \right)^6 \right] \equiv \varepsilon v \left(\frac{r}{\sigma} \right)$$

where $\varepsilon = 10.22\text{K}$ is the well depth of the potential and $\sigma = 2.556\text{\AA}$ is the core size (de Boer and Michels, 1938).

The interaction is not the very best (quantitative calculations are in fact made using the Aziz potential (Aziz et al., 1992), but it reproduces the ground state properties of the liquids within a few percent. Measuring all energies in units of the well depth, and all lengths in units of the core size, $x \equiv r/\sigma$, the Hamiltonian of the system is

Fig. 1 Normalized Lennard-Jones “6–12” interatomic potential, as a function of the normalized interatomic distance. The normalization factors for distances (σ) and potential energies (ϵ) are given in the text. We also show, for comparison, the Aziz potential (Aziz et al., 1992) which is the currently accepted most accurate static 2-body interaction.

$$\frac{1}{\epsilon} H(\mathbf{x}_1 \dots, \mathbf{x}_N) = -\frac{\Lambda^2}{8\pi^2} \sum_i \nabla_{\mathbf{x}_i}^2 + \sum_{i < j}^N (|\mathbf{x}_i - \mathbf{x}_j|) \quad (1)$$

where

$$\Lambda = \frac{h}{\sigma(m\epsilon)^{\frac{1}{2}}}$$

is de Boer’s “quantum parameter” (de Boer, 1948) Λ , giving the ratio between the de Broglie wavelength and a typical diameter of the molecule. $\Lambda \approx 2.67$ for ^4He , $\Lambda \approx 3.09$ for ^3He , but $\Lambda \approx 1.3 - 1.7$ for H_2 , HD, D_2 , and $\Lambda < 0.1$ for heavy rare gases.

Moreover, the density of ^4He at zero pressure is $\rho_0 = 0.02185\text{\AA}^{-3} = 0.365/\sigma^{-3}$ and for ^3He $\rho_0 = 0.0163\text{\AA}^{-3} = 0.273/\sigma^{-3}$, in other words the average particle distance is of the order of the core size.

^4He in 3D

Liquid helium (^4He) is the archetype of a Bose Liquid. Immediately after the discovery of the superfluidity of helium (Kapitza, 1938; Misener, 1938) by Kapitza (Moscow) and Allen and Misener (Toronto), London (1938) understood that the system was undergoing Bose-Einstein condensation, and L. Tisza proposed a “two-fluids model” featuring a coexistence of a normal fluid and a superfluid (Wilks, 1967). A Bose-Einstein condensed gas is not superfluid, however, and therefore the superfluidity observed in helium is an additional effect, associated to the interactions. A major step in the understanding of the physics of helium was made by L.D. Landau, who found a deeper interpretation of Tisza’s two-fluids model. Landau postulated that the “normal fraction,” which carries the entropy, is in fact the ensemble of thermal excitations of the superfluid ground state. This interpretation removed the unphysical consideration of two categories within a set of indistinguishable atoms. Landau considered elementary excitations of the fluid, in the form of quantized density fluctuations (phonons), similar to the Debye phonon modes of a crystalline solid. In order to calculate the thermodynamic properties by a Debye-like approach, where the energy is obtained by a sum over all modes, weighted by the Bose factor, Landau postulated that the dispersion relation $\epsilon(k)$ had a linear part $\epsilon = \hbar ck$, where c is the speed of sound, and another part displaying a minimum, the “roton gap” of energy Δ . Landau’s intuition was guided by specific heat measurements, showing a cubic temperature dependence at low temperatures (below 0.5 K), as expected from the linear part of the dispersion relation, as well as an exponential contribution at higher temperatures (on the order of 1 K), characteristic of an energy gap.

In a first article (Landau, 1941), Landau proposed a spectrum with two branches, with a parabolic branch centered at $k = 0$ in addition to the linear branch. This spectrum was not found satisfactory by Landau himself, the presence of two branches being reminiscent of Tisza’s “two kinds of atoms.”

In a second publication (Landau, 1947), he presented his celebrated “Landau dispersion relation,” where a single branch of excitations characterizes the full spectrum (Fig. 2). With two parameters, the sound velocity c and the roton gap Δ , both obtained from the temperature dependence of the specific heat, Landau’s theory provides an excellent account of the experimental properties of superfluid helium at low temperatures. The existence of a “second sound” collective mode, where the superfluid and normal components oscillate with opposite phases while keeping the total density constant, as proposed by Tisza, corresponds in Landau’s model to propagating entropy (and hence temperature) waves.

Another fundamental observation due to Landau, is that the particular shape of the dispersion relation leads to the superfluid behavior. A simple argument of energy and momentum conservation shows that the creation of excitations by the displacement of

Fig. 2 The dispersion relation proposed by L. D. Landau in 1947 to describe the elementary excitations in superfluid ^4He at zero pressure.

an object immersed in the fluid is not possible, unless the object's velocity exceeds a critical value. The linearity of the dispersion relation at low wave vectors is essential for this to happen: in a Bose gas, where the dispersion relation is parabolic, the critical velocity is zero, the system remains normal even at the absolute zero of temperature. The evolution of the dispersion relation from the parabolic shape characteristic of a gas, to the linear behavior observed as the interaction is switched on, has been explained by Bogoliubov (1947) in the weak interaction limit. The dispersion relation of the elementary excitations plays therefore a major role in the determination of the thermal properties, and also in the superfluid nature of the liquid's ground state.

Landau's phenomenological theory introduced the fruitful concept of "quasi-particles," describing in a simple way the elementary excitations of complex many-body systems. The concept was of course already present in the Debye theory of solids, but the generalization to helium, a non-periodic system of strongly interacting particles, opened a new field of physics.

There were however two serious interrogations after Landau's theory was released. The first was obviously related to the necessity of an experimental observation of the proposed dispersion curve. And the second, to the need of a microscopic theory providing some insight in the superfluid helium behavior, and able to test the validity of Landau's model.

The first microscopic theory of superfluid helium, due to Feynman (1954), is a wonderful example of physical intuition. He found a general form for a variational wave-function which successfully explained the general shape of the dispersion relation, including the roton minimum. It was soon completed by Feynman and Cohen (1956), who introduced, improving the variational wave-functions, the concept of "backflow": the flow of helium atoms around a moving helium atom.

Dealing with many-body correlations, including dynamic effects, has been central to the development of microscopic theories, which have been considerably refined in the last decades, reaching now a quantitative power of prediction, as shown below.

Experimentally, the evidence for a Landau-like dispersion relation was missing: only indirect evidence obtained from thermodynamic measurement (specific heat, thermal conductivity, viscosity, fountain pressure, etc.) was available. Feynman and Cohen suggested the use of inelastic neutron scattering, a technique already used to measure phonon dispersion curves in crystals, to try to observe the excitation dispersion curve of superfluid helium. The first proof of the existence of a roton minimum was reported by Palevsky et al. (1957), Palevsky et al. (1958), clearly showing that the elementary excitations in superfluid helium are extremely sharp, compared to those of normal helium. These exciting results motivated extensive investigations of the dynamics of helium, covering the low energy region, i.e., the Landau-like dispersion relation, the multi-excitations region at higher energies, as well as the very high energy region of the spectrum, where BEC can be investigated (Glyde, 2018).

The principle of the inelastic neutron scattering is simple, but measurements are demanding, and high flux neutron sources (reactors, spallation sources) are needed. The helium sample is placed in an incident beam of "monochromatic" (of a given energy) neutrons, which are scattered by the helium sample, and then detected at some distance from the sample, as a function of angle and time of arrival, in the so-called time-of-flight technique (Fig. 3). Other methods (triple-axis, backscattering, spin-echo, etc.) have also been used, offering a different coverage of the momentum-energy plane, and also different resolutions in energy and momentum.

Energy and momentum conservation allow the determination of the energy transfer and the momentum transfer from the neutron to the helium sample, which correspond to the energy $\varepsilon = \hbar\omega$ and momentum $\hbar\vec{k} = \hbar\vec{Q}$ of the density fluctuations created in the helium. The incident neutron has an energy E_i and a wave-vector $\vec{k}_i$, and, after scattering, a final energy E_f and a wave-vector $\vec{k}_f$; the wave-vector transfer is $\vec{Q} = \vec{k}_i - \vec{k}_f$, and the energy transfer $\hbar\omega = E_i - E_f$ (Fig. 4).

The theory of neutron scattering (Lovesey, 1984; Glyde, 1994; Glyde, 2018) relates the double differential scattering cross section per target atom, which is the parameter measured by a scattering experiment, to the dynamic structure factor $S(Q, \omega)$ and the

Fig. 3 The time-of-flight neutron scattering spectrometer IN5 at the Institut Laue-Langevin.

Fig. 4 Neutron scattering: an incident neutron of wavevector $\vec{k}_i$ creates an excitation of momentum $\hbar\vec{k} = \hbar\vec{Q}$ in the superfluid. Q is the wavevector transfer (see text).

dynamic susceptibility $\chi(Q, \omega)$, the latter being the functions calculated by microscopic theories. They are given by the following expression, where b_c is the coherent scattering length of helium:

$$\frac{\partial^2 \sigma}{\partial \Omega \partial E_f} = \frac{b_c^2}{\hbar} \frac{k_f}{k_i} S(Q, \omega) \quad (2)$$

Results are generally presented in terms of $S(Q, \omega)$, where sharp peaks of high intensity are observed, as expected from the creation of Landau “single-excitations,” as well as a more complex, broad landscape of multi-excitations. A vast literature on the subject exists, as described in the review articles by Woods and Cowley, Stirling, Glyde (see (Glyde, 2018)), the book by Glyde (Glyde, 1994), and recent works (Beauvois et al., 2018; Godfrin et al., 2021), which benefited from the substantial progress of neutron scattering facilities and instruments.

The dispersion relation $\varepsilon(k)$ of the sharp single-excitations, as measured in recent inelastic neutron scattering experiments, is shown in Fig. 5. It closely resembles the curve predicted by Landau, with a linear part at low wave-vectors (phonons), and a deep gap

Fig. 5 The dispersion relation $\varepsilon(k)$ of excitations in superfluid ^4He at zero pressure. (A) Experimental data, displaying the phonon, roton, maxon, and plateau regions of the spectrum. The red dots are recent high-accuracy, highly pixelized data (seen at this scale as a continuous line, the dispersion is only visible at the highest wave-vectors) from Godfrin et al. (2021), the blue dots with error bars are from the original work by Cowley and Woods (1971) and the green dots from the high-momentum measurements by Glyde et al. (1998). (B) theoretical results, from Feynman's model (Feynman, 1954) to modern calculations such as Brillouin-Wigner perturbation theory with correlated wave function (BW; Jackson and Feenberg, 1962; Lee and Lee, 1975), diffusion (DMC; Boronat and Casulleras, 1997; Boronat and Casulleras, 1998) and path-integral (PIMC; Ferré and Boronat, 2016) Monte Carlo calculations and dynamic many-body theory (DMBT) (Campbell et al., 2015; Beauvois et al., 2018), compared to the experimental curve (Godfrin et al., 2021).

("roton" minimum) at a wave-vector $k \sim 2\text{\AA}^{-1}$. The name roton is historical, no special rotation takes place; the minimum in energy reflects an incipient localization (short-range order), which eventually will lead to a liquid-solid transition under a pressure $P \sim 2.5\text{MPa}$. The dispersion curve becomes flat for $k \geq 2.8\text{\AA}^{-1}$ as the energy reaches twice the roton gap, forming "Pitaevskii's plateau."

The calculation of the low temperature ($T < 1.3\text{ K}$) thermodynamic properties of helium at low temperatures only involves the statistical physics of phonons and rotons of low energy. That is, the properties of the strongly interacting bosonic system are simply given by those of a collection of non-interacting bosonic "quasi-particles" described by the phonon-roton curve (Godfrin et al., 2021). At high temperatures, where the number of rotons becomes very large, roton-roton interactions start playing a role. At the "lambda point" ($T = 2.17\text{ K}$), ^4He becomes a normal fluid.

Theoretical studies of the dynamic structure function in ^4He began with the work of Feynman (1954) and Feynman and Cohen (1956), the Feynman theory of elementary excitations was developed in a systematic Brillouin-Wigner perturbation theory by Jackson and Feenberg (Jackson and Feenberg, 1961; Jackson and Feenberg, 1962; Jackson, 1969; Jackson, 1973) in terms of a basis of Feynman excitation states

$$\{|\mathbf{k}\rangle\} = \{S^{-1}(\mathbf{k})\hat{\rho}_{\mathbf{k}}|\Psi_0\rangle\} \quad (3)$$

where $\hat{\rho}_{\mathbf{k}}$ is the density operator and $|\Psi_0\rangle$ is the ground state. An important contribution was the identification of classes of theories for the dynamic structure function (Jackson, 1974) that satisfy the ω^0 and ω^1 sum rules exactly. The most complete evaluation of the phonon-roton dispersion relation in terms of Brillouin-Wigner perturbation theory was carried out by Lee and Lee (1975) who obtained an impressive agreement with the experimental phonon-roton spectrum up to the wave number of $Q = 2.5\text{\AA}^{-1}$. The major drawback with these old calculations was that the required input—pair- and three-body distribution functions—were poorly known. Manousakis and Pandharipande (1986) tried to generalize the input states of the Brillouin-Wigner perturbation theory to include “backflow” correlations in the spirit of Feynman and Cohen (1956). Through the gradient operator acting on the wave function, in principle dynamic correlations are introduced to all orders. The “backflow-function” is, however, chosen per physical intuition rather than by fundamental principles, and the evaluation of the perturbative series becomes very complicated. Topologically, diagrams similar to those of Lee and Lee (1975) were included. While the accuracy of the theoretical roton energy is comparable to that of Lee and Lee, one can clearly see an inconsistency since the energy of the Pitaevskii-plateau (Pitaevskii, 1959) lies below twice the energy of the roton gap. More recent progress (Campbell and Krotscheck, 2009; Campbell et al., 2015) used a hybrid approach of Brillouin-Wigner perturbation theory and equations of motion for time-dependent multiparticle correlation functions to derive a self-consistent theory of the dynamic density-density response of ^4He .

In a nutshell, the Feynman theory of excitations is generalized by writing the dynamic wave function as

$$\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N; t) = \exp(U(t))\Psi_0(\mathbf{r}_1, \dots, \mathbf{r}_N) \quad (4a)$$

$$U(t) = \sum_i \delta u_1(\mathbf{r}_i; t) + \sum_{i<j} \delta u_2(\mathbf{r}_i, \mathbf{r}_j; t) + \dots \quad (4b)$$

The Feynman form of the wave function is obtained by omitting all n -body fluctuations $\delta u_n(\mathbf{r}_1, \dots, \mathbf{r}_n; t)$ for $n \geq 2$. The different theoretical descriptions basically differ by the way the n -body fluctuations are determined.

Recent novel numerical methods (Boronat and Casulleras, 1998; Boronat and Casulleras, 1997; Vitali et al., 2010; Roggero et al., 2013; Nava et al., 2013) give access to dynamic properties of quantum fluids. These are important algorithmic developments that may ultimately aid in the demanding elimination of background and multiple-scattering events from the raw data. Of course, it is generally agreed upon that the model of static pair potentials like the Aziz interaction (Aziz et al., 1992) describes the helium liquids accurately. Hence, given sufficiently elaborate algorithms and sufficient computing power, such calculations must reproduce the experimental data. The aim of the works cited above is different: The identification of physical effects like phonon-phonon, phonon-roton, roton-roton, maxon-roton... couplings that lead to observable features in the dynamic structure function is, from simulation data, only possible a-posteriori whereas the semi-analytic methods permit a direct identification of these effects, their physical mechanisms, their relationship to the ground state structure, and their consequences on the analytic properties of the dynamic structure function, directly from the theory.

The dynamic structure of ^4He is actually quite rich as seen in Fig. 6 (Campbell et al., 2015; Beauvois et al., 2018): “multi-excitations” are observed at energies above the single-excitation dispersion curve discussed above. They can be related to combinations of single-excitations, some of them are indicated in Fig. 6 by colored ellipses: in blue, an extension of the linear phonon region (ghost phonon) deep into the continuum; in red, an extension of the Pitaevskii-Plateau to small wave-vectors; in green, above the roton minimum, a broadening of the dispersion relation due to a Cherenkov effect; a red dashed ellipse at high energies indicates a region of maxon-roton couplings. Multi-excitations are well reproduced by recent theories. The mechanisms behind these are mostly the same: It is kinematically possible that a perturbation of energy/momentum $(E, \mathbf{k})$ can decay into two sharp quasiparticle excitations. For example, the “ghost phonon” is caused by the effect that a perturbation can decay into two almost collinear phonons, hence the effect disappears at about twice the energy and wave number at which the dispersion relation $\varepsilon(k)$ ceases to be linear. Similarly, the “Pitaevskii-Plateau” is caused by the effect that a perturbation of energy 2Δ can decay into two rotons of energy Δ and wave number k_Δ . Hence, energy and momentum conservation dictate that the plateau ends at a wave number of $2k_\Delta$, in this case the two roton wave vectors are parallel. Perturbations with the same energy and smaller wave numbers can decay into two rotons that are not collinear. That means that the plateau can in principle extend to zero wave number; in that case the perturbation decays into two anti-parallel rotons.

The Cherenkov effect is particularly interesting; it is caused by the fact that the group velocity of a quasiparticle excitation beyond the roton (R_+ roton) is larger than the sound velocity. The effect is observed only at low pressures.

^3He in 3D

The investigation of the dynamics of the ^3He Fermi Liquid has naturally followed that of the ^4He Bose fluid (Dobbs, 2001; Glyde, 1994). From the theoretical point of view, the problem is notoriously difficult, due to the antisymmetry requirement for the

Fig. 6 Experimental (A) and theoretical (B) determinations of the dynamic structure factor of superfluid ^4He at zero pressure (upper graphs) and near-solidification pressure (lower graphs). In addition to the intense single-excitations dispersion seen in Fig. 5 (red lower curves), much lower intensity multi-excitations (see color scale) can be observed here. Colored ellipses indicate excitation couplings described in the text.

wave-functions of many-body fermionic systems (Fetter and Walecka, 1971; Thouless, 1972; Pines and Nozieres, 1966). Obtaining accurate results for the ground state is a challenge, even using very sophisticated variational wave functions.

The dynamics is treated analogously to the boson case (4b); the local excitation functions $\delta u_n(\mathbf{r}_1, \dots, \mathbf{r}_n; t)$ are replaced by particle-hole operators

$$\sum_{\substack{p_1, \dots, p_n \\ h_1, \dots, h_n}} u_{p_1, \dots, p_n; h_1, \dots, h_n}(t) a_{p_1}^\dagger \dots a_{p_n}^\dagger a_{h_n} \dots a_{h_1}$$

where the p_i are the quantum numbers of unoccupied (particle) states and the h_i those of occupied (hole) states. Restricting the excitation amplitudes to one-particle-one-hole components leads to a correlated version of the random phase approximation (RPA) (Krotscheck, 1982), the quantitative understanding of the experiments requires at least 2-particle-2-hole amplitudes, see Böhm et al. (2010), Krotscheck and Lichtenegger (2022).

From the experimental point of view, even though the same inelastic neutron techniques successfully applied to superfluid ^4He can be used to investigate liquid ^3He , in practice the experiments are extremely difficult due to the huge neutron absorption cross-section of the ^3He nucleus (Glyde, 1994). In typical ^4He experiments, sample thicknesses are larger than 1 cm, while absorption limits the maximum thickness in a liquid ^3He measurement, to about 0.1 mm. In addition, due to the lower excitation energies, experiments in ^3He must be performed at much lower temperatures ($\approx 0.1\text{K}$) than in ^4He ($\approx 1\text{K}$), to remain in the low temperature limit, where few excitations are present. For these reasons, in spite of the considerable interest in strongly interacting fermions, accurate theoretical and experimental results have been available only recently (Glyde et al., 2000).

In order to understand the dynamics of a Fermi liquid, we begin by considering the excitations of a Fermi gas. In the latter, excitations are created by removing a particle from an occupied state inside the Fermi sphere, and placing it outside the sphere, in a higher energy free state. The resulting states are confined to a region of the energy vs wave-vector space called the “particle-hole band.” The interacting fermionic system, i.e., the Fermi Liquid, behaves in a similar way. A particle-hole band can be observed in

Fig. 7 Dynamic structure factor of bulk liquid ^3He . Measured density excitations (Fåk et al., 1990) (triangles, upper branch) and spin-density excitations (Glyde et al., 2000) (squares, lower branch) are clearly visible (bars on the data points indicate the observed width of the branch). Color intensity map, from light blue to dark red: DMBT microscopic theory including exchange (Krotscheck and Lichtenegger, 2022). The solid lines indicate the boundaries of the particle-hole band.

bulk ^3He (see Fig. 7), but in addition, collective modes are present. A density mode, named “zero-sound” or “collision-less sound,” is observed. Its physical origin, as noted by Pines (1981), resides in the strong interactions, and hence this mode is analogous to the phonon-roton mode described above for bosons; statistics play here a minor role. Its substantial energy width results from the possibility to decay into particle-hole excitations as it enters the particle-hole band (Landau-damping mechanism).

The thermodynamic properties of bulk liquid ^3He are often described, at very low temperatures, by the phenomenological Landau Fermi Liquid model, where the properties of the interacting system are related to those of the Fermi gas by the introduction of an interaction function (quasiparticle interaction), leading to a renormalization of parameters (effective mass, susceptibility enhancement, etc.). Landau theory predicts, among other physical effects, the existence of collective modes, the zero-sound and paramagnon modes.

Landau’s Fermi Liquid Theory is only applicable at very low temperatures. In liquid ^3He , where the Fermi energy, expressed in temperature units, is of the order of several kelvins, the theory is valid below 0.1 K.

The reason becomes clear if one observes the actual excitation spectrum shown in Fig. 7. The low energy mode, observed below the zero-sound excitation, is a spin-density mode, completely immersed in the particle-hole band, and hence severely Landau-damped. The origin of this mode, analogous to a dampened spin-wave and often called “paramagnon,” can be traced back directly to the antisymmetry of the many-body wave function.

There are also some interesting X-ray studies of the dynamic structure function at high momentum transfers (Albergamo et al., 2007) that have led to a discussion about the location of the particle-hole band (Schmets and Montfrooij, 2008; Albergamo et al., 2008). The authors of Albergamo et al. (2007) state that *The obtained results show no evidence of such a decay: the zero-sound mode remains well defined in the whole explored wave number range.* According to that, the particle-hole continuum should be much lower than the continuum of the non-interacting Fermi system. An analysis of both the data and the theoretical predictions within DMBT (Krotscheck and Panholzer, 2011) shows that there is, when the theoretical data are convoluted with the experimental resolution, actually no contradiction to the conventional interpretation of the scenario.

Details are shown in Fig. 8. To facilitate the comparison with experiments, the theoretical spectra were convoluted with the experimental resolution. Also, the results were scaled by $1/S(k)$ such that the integrated strength is 1 for all momentum transfers. The same scaling was applied to the experimental data.

^4He in reduced dimensions

The dynamics of quantum fluids has also been investigated in reduced dimensions. Two-dimensional (2D) systems are obtained experimentally by adsorption of gases onto solid substrates, usually graphite. One-dimensional (1D) systems can also be created, they are obtained by confining the gases inside silica or graphite nano-tubes (Yano et al., 1998; Kato et al., 1987; Del Maestro et al., 2022). There is also theoretical interest (Stan and Cole, 1998; Stan et al., 1998; Bertaina et al., 2016; Krotscheck and Miller, 1999; Gordillo et al., 2000) in the properties of ^4He in one-dimension.

Extensive theoretical studies have clarified the nature of the excitations in such systems. Superfluid ^4He films of atomic thicknesses, for instance, display in-plane density modes, as well as capillary waves.

Let us first discuss the dynamics of rigorously 2D ^4He . Basically we see the same effects as in 3D: a linear “phonon” branch as well as, at high momentum transfers, a “roton minimum.”

One can also see the somewhat finer details discussed above: At low densities, the “ghost-phonon,” and at high densities the plateau coming down and extending to long wave lengths. A second striking feature is the appearance of a sharp mode below the plateau. We stress the difference: normally, the plateau is a threshold above which a wave of energy/momentum ($\hbar\omega, k$) can decay into two rotons. This has the consequence that the imaginary part of the self-energy $\Sigma(k, \hbar\omega)$ is a step function and the real part has a

Fig. 8 The figure shows the normalized dynamic structure function $S(k, \omega)/S(k)$ of ^3He at a density of $\rho = 0.0166\text{\AA}^{-3}$, for a sequence of wave numbers. The theoretical results obtained by DMBT (Krotscheck and Panholzer, 2011) are compared with the X-ray scattering data (Albergamo et al., 2007) (squares) at saturated vapor pressure. Also shown are the theoretical results convoluted with the experimental resolution (dashed lines). The gray-shaded area shows the particle-hole continuum of a non-interacting Fermi fluid. $t_F = \hbar^2 k_F^2 / 2m$ is the Fermi energy of the non-interacting system.

logarithmic singularity (Pitaevskii, 1959). A collective mode is, on the other hand, characterized by a singularity of the $S(k, \hbar\omega)$. Fig. 9 shows, for the two highest densities, the appearance of a sharp discrete mode *below* the plateau. At a wave number of $k \approx 2.6\text{\AA}^{-1}$, the collective mode is still merged into the continuum. With increasing wave number, we see, however, a clearly distinguishable but rather weak ($Z(k) \approx 0.02$) mode about 0.3 K below the plateau. We have mentioned already above that the roton should be seen as an emergence of short-ranged order, the “ghost of a Bragg Spot” (Nozières, 2004; Nozières, 2006). If this is the case, then one might see a second Bragg spot. Such a thing is not seen, but location of the secondary minimum in 2D corresponds indeed to the position of a second Bragg spot of a triangular lattice.

Density modes (Krotscheck and Lichtenegger, 2015) are analogous to the phonons and rotons already mentioned in the case of bulk helium, but due to the adsorption potential of the substrate, the fluid is inhomogeneous, and solidification of the first two or three atomic layers is observed in thick films. Layered-excitations are observed in this regime.

Capillary waves, also called “ripples,” have a different nature: these are surface waves, which do not (in first approximation) correspond to compression/expansion of the fluid, but to a change of height in the external potential (gravitational in the case of a bulk helium surface, or substrate potential in adsorbed films).

A typical example is shown in Fig. 10. It corresponds to a multilayer film of about 6 atomic layers, where both density excitations and ripples are visible with comparable intensity (Lauter et al., 1992). The experimental curve is broader than the theoretical one, an effect largely due to the mosaic spread (angular distribution) of the graphite substrate, a powder made of microscopic flat crystals.

Finally, in the sub-monolayer coverage regime, one can observe gaseous, fluid and solid phases, as well as “commensurate phases” where the atoms adopt a periodic arrangement commensurate with the substrate atomic lattice.

Fig. 9 The figure shows contour plots of the dynamic structure function of two-dimensional liquid ^4He for a sequence of areal densities as shown in the legends. The colors have been chosen to highlight the prominent features, darker colors correspond to higher values of $S(k, \hbar\omega)$. We also show the Feynman spectrum, and the simulation data of Arrigoni et al. (2013). From Krotscheck E and Lichtenegger T (2015) *Journal of Low Temperature Physics* 178: 61.

^3He in reduced dimensions

The excitations in ^3He films are shown in Fig. 11. They are very similar to those discussed above for bulk liquid, with the remarkable exception (Godfrin et al., 2012) that the roton-like excitations are at the edge of the particle-hole band and hence not strongly affected by Landau damping. These excitations can therefore propagate, suggesting interesting physical effects specific to 2D Fermi liquids.

Conclusion

The investigation of the dynamics of quantum fluids has been performed experimentally at very low temperatures using various techniques, mainly specific heat, compressibility, neutron and X-ray scattering and, for ^3He , nuclear magnetic susceptibility. Theoretical calculations are based on semi-phenomenological approaches (Aldrich and Pines, 1976; Aldrich III and Pines, 1978; Hsu and Pines, 1985), dynamic many body theory (DMBT) (Böhm et al., 2010; Campbell et al., 2015; Krotscheck and Lichtenegger, 2022) as well as different versions of Quantum Monte Carlo numerical calculations (PIMC, DMC) (Boronat and Casulleras, 1997; Ferré and Boronat, 2016; Arrigoni et al., 2013; Bertaina et al., 2016) to cite only a few. These have brought a very detailed understanding of these systems. It is sometimes very difficult to perform experimental measurements on some particular systems (for instance in reduced dimensionality), or even impossible to create quite arbitrary systems (“mathematical models” of interaction or external potentials, etc.). In this case the combination of numerical and microscopic techniques is essential.

Fig. 10 Experimental (Lauter et al., 1992) (A) and theoretical (B) (Clements et al., 1996) determinations of the dynamic structure factor of a multilayer film of ^4He , displaying density and ripplon excitations.

The results find a natural application to many different physical systems, like nuclear matter, neutron stars, particle physics and cosmology, where strongly interacting particles are investigated. Particles themselves, in fact, can be interpreted as quantized excitations of an underlying field. The helium liquids have been, in some sense, the Ariadne thread in these investigations: Their interactions are well established (Aziz et al., 1979; Aziz et al., 1987) and, compared to nucleon interactions, quite simple. The density of these systems is very high and they are very “quantum,” hence they do not permit the simple treatments that have become popular by the experimental success to generate and investigate cold quantum gases. The experimental challenge is equally high and only the very best of the experimental equipment and the experimental techniques can stand up to the challenge. Nevertheless, these challenges have been met on both the theoretical and experimental side.

Fig. 11 Experimental (A) and theoretical (B) determinations of the dynamic structure factor of two-dimensional liquid ^3He (Godfrin et al., 2012). The theoretical calculation shows the density and spin-density modes; the latter is not visible experimentally, it is masked by a strong elastic signal due to the substrate. A comparison with Fig. 7 shows that the roton-like excitation in the 2D system is found outside the particle-hole band (the region limited by the blue solid lines), thus avoiding Landau damping.

Abstract

In this Chapter, we give a brief review of the state of the art of theoretical and experimental studies of quantum fluids of light. Such systems consist of ensembles of photons that acquire a finite mass from spatial confinement or diffraction and finite binary interactions from the optical nonlinearity of the optical medium. The peculiar properties of these fluids are highlighted in comparison with standard condensed matter systems, with a special emphasis on the novel possibilities that they offer for the generation, the manipulation and the diagnostics of the fluid, as well as on their intrinsically non-equilibrium and/or dynamical nature. Perspectives toward a new generation of experiments on strongly correlated fluids of light and toward opto-electronic applications are finally sketched.

Key points

This chapter aims to

- Illustrate the general concept of quantum fluid of light and the necessary ingredients
- Highlight the role of non-equilibrium physics under the effect of driving and dissipation in quantum fluids of light in cavity set-ups
- Introduce the $t \leftrightarrow z$ mapping underlying quantum fluids of light in propagating geometries
- Highlight the exciting perspectives in the direction of realizing strongly correlated fluids of light
- Briefly summarize how quantum fluids of light can be useful for opto-electronic and quantum applications

Introduction

Traditionally, our pictures of matter and light are very different.

Matter consists of material objects, that can be touched with our fingers and mechanically react to our manipulation in very different ways. For instance, solid matter is rigid; one can take advantage of the weight of liquid matter to float and of its internal friction to swim; complex fluidodynamic phenomena are exploited by birds and aircrafts to fly through gaseous media. At a more sophisticated level, quantum fluids combine hydrodynamics with quantum mechanical features and display a variety of exotic behaviors, from superfluidity in liquid Helium and ultracold atomic clouds (Pitaevskii and Stringari, 2016), to superconductivity in electron gases (Tinkham, 2004), to quantized conductance of incompressible quantum Hall fluids in the presence of strong magnetic fields (Tong, 2016). At completely different scales of energy, exciting properties has been unveiled in the nuclear matter that forms atomic nuclei or neutron stars (Ring and Schuck, 2004).

On the contrary, light is associated to a flow of electromagnetic waves or, in a quantum description, of corpuscular photons that fly through space at the universal speed c from the emitter to the absorber (Walls and Milburn, 2006). The interesting physics occurs in between, and, in standard configurations, it consists of some in-fly modification of the properties of the beam. Of course this can be extremely rich and diverse, and may involve the interplay of reflection and refraction effects with wave interference phenomena, nonlinear optical processes due to the coupling to electronic transitions in material media, and even quantum effects due to the discrete nature of the photon. Still, all these phenomena are associated to the idea of light has to necessarily keep propagating all the time and cannot be stored in some container so to be manipulated as one normally does with matter.

The concept of *Quantum Fluid of Light* (QFL) defies this duality and merges concepts from condensed matter physics and optics to investigate the new collective physics that light displays when it is confined and, then, manipulated as a standard fluid of many interacting photons. This exotic behavior of course requires very specific conditions to happen: in particular one needs photons to acquire some finite mass and display significant inter-particle interactions (Carusotto and Ciuti, 2013).

Fig. 1 Effective mass for photons confined in planar microcavities. (Upper panel) Scheme of the device and of the field configuration. (Lower panel) Relativistic in-plane dispersion of photons in the planar cavity.

From special relativity, we know that massless particles propagate at a fixed speed c and a finite *mass* is needed to put particles at rest. Photons are naturally massless particles, but may acquire a finite effective mass when they are confined in space, e.g., in between a pair of plane-parallel metallic mirrors as it is sketched in the top panel of Fig. 1. In this simplest configuration, the wavevector along the normal z direction is quantized as $k_z^{(q)} = \pi n / L_z$ in terms of the positive integer number q while the in-plane motion remains free and acquires a massive relativistic-like dispersion,

$$\omega^{(q)}(\mathbf{k}_{\parallel}) = ck_z^{(q)} + \frac{1}{2k_z^{(q)}} \mathbf{k}_{\parallel}^2 \quad (1)$$

that is plotted in the lower pane of the same Figure. The finite effective mass $m^{(q)}$ arising from the zero-point confinement along z is such that

$$m^{(q)}c^2 = \hbar ck_z^{(q)} \quad (2)$$

and grows with the quantum number q , i.e., the number of nodes of the field in the z direction. As usual, its role is twofold: as a *rest mass*, it gives the forbidden energy gap below the dispersion; as the *kinetic mass*, it gives the curvature of the dispersion around $\mathbf{k}_{\parallel} = 0$. A most celebrated family of experiments works with the lowest $q = 1$ band of planar semiconductor microcavities enclosed by dielectric mirrors (Carusotto and Ciuti, 2013), but a number of other exciting configurations have also been explored with peculiar properties (Schine et al., 2016).

In contrast to the linearity of Maxwell equations which guarantees a superposition principle for light fields (Jackson, 1999), photon-photon interactions naturally arise in QED from the coupling of light with the electron-positron quantum field (Heisenberg and Euler, 1936). The simplest Feynman diagram describing photon-photon interactions is sketched in the left panel of Fig. 2, and corresponds to an effective two-photon collision mediated by the creation of virtual electron-positron pairs. In any table-top experiment, the scattering cross-section corresponding to these Heisenberg-Euler processes.

$$\sigma \propto \alpha^4 \left(\frac{\hbar}{m_{el}c} \right)^2 \left(\frac{\hbar\omega}{m_{el}c^2} \right)^6 \quad (3)$$

is however suppressed not only by the four fine-structure $\alpha = e^2/\hbar c \sim 1/137$ factors stemming from the four interaction vertices and by the small value $\hbar/(m_{el}c) \simeq 2.4\text{pm}$ of the electron Compton wavelength, but also, and much more dramatically, by the energy denominators corresponding, within perturbation theory, to the virtual intermediate states. For visible or infrared light for which

Fig. 2 Basics of photon-photon interactions: (left) Feynman diagram describing interactions mediated by virtual electron-positron pairs in QED; (right) scheme of the energy levels involved in the photon blockade effect in a nonlinear optical cavity.

photons have an energy at most in the few eV range, these are dominated by the rest mass of the virtual electron-positron pair which lies in the MeV range and, via the last factor in (3) give a huge 10^{-36} suppression factor. As a result, the direct observation of photon-photon scattering in vacuo appears extremely challenging and some experimental evidence was only reported for special configurations based on gamma-rays hitting the ultraintense quasi-bound electric field of a heavy-ion (ATLAS Collaboration, 2017).

The mathematical form of (3) also suggests possible way-outs to this difficulty: at a simplest level of description, the elementary excitations of solid-state insulating materials consist of electrons and holes, i.e., missing electrons in an otherwise filled valence band, which play a very similar role to positrons in vacuo (Ashcroft and Mermin, 2022). On the basis of this analogy, it is therefore immediate to expect an enormous reinforcement of the photon-photon scattering cross-section as, in a typical solid-state material, the energy detuning denominator in (3) involves the width of the energy gap in the eV range, and the last factor is thus of order one. This intuitive expectation is fully confirmed by all those nonlinear optical effects that are commonly observed using standard laser sources and can be reinterpreted in terms of photon-photon interaction vertices (Boyd, 2008; Butcher and Cotter, 2008). Even though this is very oversimplified view and cutting-edge experiments are based on more sophisticated media, still it offers a useful intuition of the underlying physics. A most efficient strategy to reinforce the optical nonlinearity is to mix the cavity photon mode with some electronic excitation, e.g., an excitonic transition in a quantum well embedded in the cavity layer, and work with the resulting mixed quasi-particles, the so-called exciton-polaritons (Kavokin et al., 2011).

Further enhancements can be obtained using more sophisticated optical set-ups or engineered meta-materials, so to bring the system into a regime completely at odd with the linear Maxwell equations, where photons behave as impenetrable particles (Chang et al., 2014). After a number of pioneering demonstrations (Birnbaum et al., 2005), the most celebrated and promising advances in the direction of strongly interacting fluids of light have been obtained using dressed optical photons in atomic gases in the so-called Rydberg-EIT (Electromagnetically Induced Transparency) regime (Peyronel et al., 2012) or microwave photons confined in superconductor-based circuits in the so-called circuit-QED devices (Blais et al., 2021; Carusotto et al., 2020). In both cases, the idea is that the refractive index change induced by the optical nonlinearity in the field of a single photon is already sufficient to significantly affect the propagation of the following photons that attempt to penetrate the same spatial region.

The simplest example of such phenomenon is the so-called *photon blockade* effect (Imamoglu et al., 1997): when a single-mode cavity is filled by a $\chi^{(3)}$ nonlinear medium, the dynamics of the e.m. field can be described as a nonlinear oscillator of Hamiltonian

$$H = \hbar\omega_o \hat{a}^\dagger \hat{a} + \hbar\omega_{nl} \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} \quad (4)$$

whose quantum eigenstates are labeled by the number of photons and have an energy $E_n = n\hbar\omega_o + \frac{n(n-1)}{2}\hbar\omega_{nl}$ as sketched in the right panel of Fig. 2. Since the separation $E_{n+1} - E_n = \hbar\omega_o + (n+1)\hbar\omega_{nl}$ grows with n , an incident field tuned to resonance with the $0 \rightarrow 1$ transition is detuned from the $1 \rightarrow 2$ transition by an effective interaction energy $U = \hbar\omega_{nl}$. As a result, if the nonlinearity exceeds the cavity linewidth $\omega_{nl} \gg \gamma$, the second transition is effectively suppressed and the cavity behaves as an effective two-level system which can only host one photon at a time as if photons were impenetrable objects.

In the following Sections we are going to review some among the most exciting advances that the concept of Quantum Fluid of Light has given in the last decades and, in particular, of the new fundamental insight that it has given to the physics of fluids in novel non-equilibrium regimes. Section “Microcavity devices: Non-equilibrium physics” and “Propagating geometries: Conservative dynamics” will be devoted to a brief presentation of the two main conceptual classes of platforms for quantum fluids of light, namely microcavity and propagating geometries. Then, in Section “Strongly correlated fluids and topological states of photonic matter” we will review the on-going research in the direction of strongly correlated fluids of light and topological states of photonic matter. Finally, in Section “Conclusion” we will draw some conclusions and we will sketch future perspectives for the field.

Microcavity devices: Non-equilibrium physics

Combining the elements presented in the previous Section, the in-plane dynamics of quantum fluids of light in microcavity configurations turns out to be well captured by a bosonic Hamiltonian of the usual form,

$$H = \int d\mathbf{r} \left[\hbar\omega_o \hat{\Psi}^\dagger(\mathbf{r})\hat{\Psi}(\mathbf{r}) + \frac{\hbar^2}{2m^*} \nabla \hat{\Psi}^\dagger(\mathbf{r}) \nabla \hat{\Psi}(\mathbf{r}) + \frac{\hbar g_{nl}}{2} \hat{\Psi}^\dagger(\mathbf{r}) \hat{\Psi}^\dagger(\mathbf{r}) \hat{\Psi}(\mathbf{r}) \hat{\Psi}(\mathbf{r}) \right] \quad (5)$$

whose terms describe, in order, the effective rest energy of the photons, their kinetic energy associated to the kinetic mass, and their (contact) interactions mediated by the optical nonlinearity. This Hamiltonian clearly shows the microscopic processes at play in the quantum fluid of light and their direct equivalence to an ordinary gas of material particles. As such, it is the cornerstone of most theoretical descriptions of the quantum fluid of light (Carusotto and Ciuti, 2013).

In addition to the conservative evolution described by the Hamiltonian (5), in any realistic configuration one needs to take into account the different loss channels to which photons are naturally subject, in particular radiative losses through the cavity mirrors. In any experiment, the unavoidable radiative losses must therefore be compensated by some continuous pump mechanism to replenish the fluid. This is perhaps the most relevant peculiarity of quantum fluids of light in cavity geometries as compared to standard fluids of material particles and is sketched in Fig. 3.

Combining the conservative and the driven-dissipative parts of the evolution, the overall dynamics of a weakly interacting fluid of light can be summarized by a generalized driven-dissipative form of Gross-Pitaevskii equation for the expectation value of the Bose field operator $\psi = \langle \hat{\Psi} \rangle$ describing the in-cavity electromagnetic field,

$$i \frac{\partial \psi}{\partial t} = \left[\omega_o - \frac{\hbar \nabla^2}{2m^*} \right] \psi + g_{nl} |\psi|^2 \psi + \frac{i}{2} \left[\frac{P}{1 + |\psi|^2/n_s} - \gamma \right] \psi + E_{inc}(\mathbf{r}, t) \quad (6)$$

where the first and second lines respectively include the conservative evolution and the driven-dissipative terms describing saturable incoherent pumping, losses, and coherent pumping by an external laser field.

In contrast to early belief, the presence of losses is however not just a hindrance and the ensuing driven dissipative nature of the fluid provides additional experimental knobs. On the one hand, suitably designed incident light fields can in fact be used to inject the photon fluid with the desired spatio-temporal profile and then probe its properties. On the other hand, since all properties of the in-cavity field directly transfer to the radiated field, the state of the fluid of light can be experimentally reconstructed up to its most subtle quantum correlations just by performing quantum optical measurement on the emitted light Walls and Milburn (2006).

From a wider perspective, these features constitute important assets that enlarge the possibilities of quantum fluids of light well beyond what is normally possible with standard material fluids. Even when the pump and the dissipation establish a dynamical

Fig. 3 Sketch of a superfluidity experiment with a fluid of light in a planar microcavity geometry. Figure inspired to the theory and experiments in Amo et al. (2009) and Carusotto and Ciuti (2004). For the parameters in the figure, the photon fluid flows faster than the critical speed for superfluidity: a significant intensity modulation appears in the near-field intensity profile (i.e., the spatial density distribution of photons) and a deformed-ring-shaped pattern appears in the far-field one (i.e., the in-plane momentum distribution).

equilibrium, the resulting Non-Equilibrium Steady-State (NESS) is not necessarily thermalized and may display novel features stemming from the non-equilibrium nature. Such a feature was first highlighted in the early '70s when a connection was drawn (Graham and Haken, 1970) between laser operation and non-equilibrium phase transitions and turned out to play a central role in the numerous studies of non-equilibrium Bose-Einstein condensation effects in fluids of light (Bloch et al., 2022). Dramatic observable consequences of the non-equilibrium condition have also been observed in different properties of the fluid, from the possibility of condensing into excited states (Richard et al., 2005; Wertz et al., 2010), to the onset of diffusive rather than sonic collective Goldstone modes (Szymańska et al., 2006; Wouters and Carusotto, 2007), to subtle features in the definition of superfluid critical velocities (Wouters and Carusotto, 2010), to peculiar spatio-temporal correlations in the Kardar-Parisi-Zhang universality class (Fontaine et al., 2022), just to quote a few examples.

Propagating geometries: Conservative dynamics

A conceptually different class of fluids of light originates from the formal analogy between the paraxial propagation equation for the complex-valued amplitude of monochromatic light in nonlinear bulk media

$$i \frac{\partial \mathcal{E}}{\partial z} = -\frac{1}{2\beta_0} \nabla_{\perp}^2 \mathcal{E} + V(\mathbf{r})\mathcal{E} + G_{\text{nl}}|\mathcal{E}|^2 \mathcal{E} \quad (7)$$

and the Gross-Pitaevskii equation of the dynamics of dilute two-dimensional superfluids: diffraction in the transverse xy plane provides the effective mass term, the transverse refractive index profile induces an external potential $V(\mathbf{r}) = -\beta_0 \delta \varepsilon(\mathbf{r})/(2\varepsilon_0)$, and the intensity-dependent dielectric constant provides photon-photon interactions of strength

$$G_{\text{nl}} = -\frac{\beta_0 \chi^{(3)}}{2\varepsilon_0}. \quad (8)$$

Here, $\beta_0 = \varepsilon_0^{1/2} \omega_0/c$ is the propagation constant of light at frequency ω_0 in the medium and $\varepsilon = \varepsilon_0 + \chi^{(3)}|\mathcal{E}|^2$ is the nonlinear, intensity-dependent dielectric constant. In this formalism, the slowly-varying complex amplitude $\mathcal{E}$ is related to the real-valued physical electric field E by

$$E(\mathbf{r}, t) = \mathcal{E}(\mathbf{r}) e^{i\beta_0 z} e^{-i\omega_0 t} + \text{c.c.} \quad (9)$$

In the last decades, this configuration has been long used to observe a variety of hydrodynamic phenomena, from optical vortices (Couillet et al., 1989) to superfluid features (Fontaine et al., 2018), to condensation of classical light (Baudin et al., 2020; Krupa et al., 2017). As a most important conceptual difference from the cavity geometries considered in the previous Section, the role of time is played in these experiments by the propagation coordinate z . On the other hand, the use of monochromatic light imposes a rigid $e^{-i\omega t}$ form to the time-dependence of the field.

While this has not been a major concern as long as people were interested in hydrodynamics effects at the mean-field level of (7), a more sophisticated theoretical model is required to describe quantum phenomena related to the corpuscular nature of the photons. In particular, one needs to develop a theory that is not restricted to monochromatic beams and is able to include a fullfledged temporal dynamics of the field amplitude $\mathcal{E}(\mathbf{r}, t)$.

A most convenient way to do this is to start from the full classical propagation equation for the spatio-temporal electric field amplitude $\mathcal{E}(\mathbf{r}, t)$ (Agrawal, 2001; Rosanov, 2002). Seen from a comoving frame where $\bar{t} = t - z/v_g$, such an equation has again a Gross-Pitaevskii form.

$$i \frac{\partial \mathcal{E}}{\partial z} = -\frac{1}{2\beta_0} \nabla_{\perp}^2 \mathcal{E} + \frac{D_0}{2} \frac{\partial^2 \mathcal{E}}{\partial \bar{t}^2} + V\mathcal{E} + G_{\text{nl}}|\mathcal{E}|^2 \mathcal{E}, \quad (10)$$

yet in three-dimensions: the propagation distance z plays the role of a temporal coordinate, and the physical time $\bar{t}$ becomes a third spatial coordinate together with the transverse $\mathbf{r}_{\parallel} = (x, y)$ ones. Here, we have assumed to work with a relatively narrowband signal centered around a frequency ω_0 that propagates at a group velocity $v_g = (\partial k_z / \partial \omega)^{-1}$. The effective mass in the temporal direction is determined by the group velocity dispersion $D_0 = \partial^2 k_z / \partial \omega^2$. In addition to a spatial dependence, the potential due to the dielectric constant modulation may also display a temporal dependence, $V(\mathbf{r}, t)$.

This classical field equation can be promoted to a quantum model by means of a non-standard quantization procedure based on the so-called $t \leftrightarrow z$ mapping (Lai and Haus, 1989a, 1989b; Larré and Carusotto, 2015b). In contrast to the usual canonical quantization where commutation rules are imposed between operators at the same time t and different spatial position $\mathbf{r}, \mathbf{r}'$, here the commutation rules are to be imposed between conjugate field operators at the same z position but different rescaled times $\zeta = v_g \bar{t}$ and different positions $\mathbf{r}_{\parallel}$ along the transverse plane,

$$\left[\hat{\mathcal{E}}(\mathbf{r}_{\parallel}, \zeta; z), \hat{\mathcal{E}}^{\dagger}(\mathbf{r}'_{\parallel}, \zeta'; z) \right] = \frac{2\pi\hbar\omega_0^2 v_g}{\beta_0 c^2} \delta^{(2)}(\mathbf{r}_{\parallel} - \mathbf{r}'_{\parallel}) \delta(\zeta - \zeta'). \quad (11)$$

To complete the $t \leftrightarrow z$ mapping, we replace the propagation coordinate z with the temporal variable $\tau = z/v_g$ and write a bosonic Hamiltonian in the usual form, where spatial integration is now taken over the three dimensional space $R = (\mathbf{r}_{\parallel}, \zeta)$,

$$H = \frac{\beta_0 c^2}{2\pi\omega_0^2} \int d^3R \left[\frac{1}{2\beta_0} \nabla_{\parallel} \hat{\mathcal{E}}^{\dagger} \nabla_{\parallel} \hat{\mathcal{E}} - \frac{D_0 v_g^2}{2} \frac{\partial \hat{\mathcal{E}}^{\dagger}}{\partial \zeta} \frac{\partial \hat{\mathcal{E}}}{\partial \zeta} + V \hat{\mathcal{E}}^{\dagger} \hat{\mathcal{E}} + \frac{\hbar G_{\text{nl}}}{2} \hat{\mathcal{E}}^{\dagger} \hat{\mathcal{E}}^{\dagger} \hat{\mathcal{E}} \hat{\mathcal{E}} \right]. \quad (12)$$

A quantum version of the paraxial propagation equation (10) then naturally arises from the Heisenberg motion equation stemming from this Hamiltonian,

$$i \frac{d\hat{\mathcal{E}}}{d\tau} = \frac{1}{\hbar} [\hat{\mathcal{E}}, H] = v_g \left[-\frac{1}{2\beta_0} \nabla_{\perp}^2 \hat{\mathcal{E}} + \frac{D_0 v_g^2}{2} \frac{\partial^2 \hat{\mathcal{E}}}{\partial \zeta^2} + V \hat{\mathcal{E}} + G_{\text{nl}} \hat{\mathcal{E}}^{\dagger} \hat{\mathcal{E}} \hat{\mathcal{E}} \right] \quad (13)$$

where the v_g factor on the right-hand-side accounts for the $z = v_g \tau$ relation of the $t \leftrightarrow z$ mapping.

From the physical point of view, the main difference with respect to the cavity configurations considered in the previous Section is that the field dynamics in propagating geometries is not intrinsically subject to dissipation. Provided the nonlinear medium is transparent on the length scale of the experiment, the light field follows in fact a conservative Hamiltonian evolution similar to the one of cold atomic gases. In contrast to atomic gases, however, the fluid of light is typically found in conditions far from thermal equilibrium condition: as it is sketched in Fig. 4 rather than starting from a thermal equilibrium state, the initial condition of the quantum dynamics is imposed by the quantum state of the light field incident on the front face of the optical medium. Also in this case, all properties of the final state can be experimentally accessed by means of quantum optical measurements on the transmitted light.

From a theoretical point of view, this quantum theory of propagating light still relies on heuristic arguments and the $t \leftrightarrow z$ mapping procedure is still awaiting a formal mathematical proof. Yet, first experimental evidence of quantum effects has been reported for a fluid of light subject to a sudden quench of the interaction constant (Steinhauer et al., 2022). This suggests that propagating light is as another promising platform where to study the quantum dynamics of interacting many-body systems.

Strongly correlated fluids and topological states of photonic matter

In the previous Sections, we have highlighted a number of exciting hydrodynamic phenomena that take place in weakly interacting fluids of light. Most of these effects are accurately described via classical field equations that generalize the well-known Gross-Pitaevskii equation of dilute Bose-Einstein condensates to the novel context. The new frontier is now to explore regimes where the optical nonlinearities are so important that photons are strongly interacting particles and the fluid develops strong quantum correlations. In this case, a full quantum many-body description is typically required and, in analogy to related work in cold atomic gases (Bloch et al., 2008), a variety of exotic physical phenomena are expected to arise.

Interesting steps in this direction have been carried out in both microcavity and propagating geometries and closely connect to the on-going research on single-photon nonlinear optics (Chang et al., 2014). A basic building block in view direction is the photon blockade phenomenon already discussed in the introductory section. Beyond the single-mode cavity set-ups in which photon blockade was originally studied (Birnbaum et al., 2005; Imamoglu et al., 1997), strongly interacting fluids of light are now starting to be investigated both in multi-mode cavity geometries as well as in propagating geometries.

Fig. 4 Sketch of a superfluidity experiment with a fluid of light in a propagating geometry. Figure inspired to the theory and experiments in Larré and Carusotto (2015a) and Michel et al. (2018). Also in this figure, the parameters are chosen to have a flow speed faster than the critical speed for superfluidity and clear patterns appear in both the near- and the far-field profiles of the transmitted beam.

On the former side, a most remarkable accomplishment has been the experimental realization of a Mott insulator state of impenetrable photons in an array of nonlinear superconductor-based cavities for microwave photons (Ma et al., 2019). On the latter side, a marked antibunching has been observed in the transmitted light after propagation through a strongly nonlinear medium formed by dressed atoms in the Rydberg-EIT configuration (Peyronel et al., 2012). For a different level configuration providing attractive rather than repulsive photon-photon interactions, experimental evidence of two-photon bound states was also reported (Firstenberg et al., 2013).

An even richer variety of strongly correlated phases of matter has been anticipated to arise in fluids of light in the presence of synthetic magnetic fields and/or in topological photonic structures (Ozawa et al., 2019): in spite of the electric neutrality of the photon, photonic configurations have been in fact explored where light propagation is subject to analogs of the Lorentz force acting on charged particles in magnetic fields. As a most celebrated experimental observation, unidirectional light propagation on chiral edge states has been demonstrated for photonic lattices with topologically non-trivial band structures (Hafezi et al., 2013; Rechtsman et al., 2013; Wang et al., 2009). More recently, *topological laser* devices have been demonstrated in topological lattices endowed with gain (Bahari et al., 2017; Bandres et al., 2018; St-Jean et al., 2017): in addition to being a promising device for opto-electronic applications, such systems can be seen as a novel example of quantum fluid of light living in a chirally moving one-dimensional geometry and with peculiar statistical properties (Amelio and Carusotto, 2020). Further exciting perspectives are offered by the so-called *synthetic dimensions*, which allow to realize quantum fluids of light living in high-dimensional geometries beyond the usual three spatial dimensions (Ozawa and Price, 2019).

In combination with strong photon-photon interactions, topological photonic systems have been anticipated to lead to optical analogs of fractional quantum Hall physics (Kapit et al., 2014; Umucalılar and Carusotto, 2012). Among the most remarkable pioneering experimental results in this direction, we can mention the chiral currents observed in a few-site plaquette for strongly interacting microwave photons (Roushan et al., 2017) and the realization of baby Laughlin liquids in twisted cavities for visible photons (Clark et al., 2020). Motivated by these early achievements, a strong activity is presently in progress in the international community toward the realization of macroscopic samples of topological states of photonic matter (Kurilovich et al., 2021).

Conclusion

The exciting advances that we have summarized in this Chapter provide an overview of the intriguing physics of quantum fluids of light and suggest the promising developments that one may anticipate for this field of research in the next future. After decades where hydrodynamic descriptions of optical systems have been considered as just a mathematical analogy and an intellectual curiosity, the recent advances have demonstrated how the physical picture of light as an ensemble of interacting photons provides a novel example of condensed matter system where to explore, in particular, uncharted lands of nonequilibrium quantum many-body physics.

A further interest for these systems comes from the straightforward inclusion of quantum fluids of light in devices for opto-electronic applications: the close relationship between lasing and Bose-Einstein condensation has been known for decades (Graham and Haken, 1970), but has received a renewed interest in the last years with the development of novel concepts of coherent light sources (Bloch et al., 2022). On a longer run, an even more ambitious application could be to realize a topological quantum computing architecture (Nayak et al., 2008) based on topological states of photonic matter.

Abstract

Quantum systems driven by a time-periodic field are a platform of condensed matter physics where effective (quasi) stationary states, termed “Floquet states,” can emerge with external-field-dressed quasiparticles during driving. They appear, for example, as a prethermal intermediate state in isolated driven quantum systems or as a nonequilibrium steady state in driven open quantum systems coupled to environment. Floquet states may have various intriguing physical properties, some of which can be drastically different from those of the original undriven systems in equilibrium. In this article, we review fundamental aspects of Floquet states, and discuss recent topics and applications of Floquet states in condensed matter physics.

Key points

- Introduce Floquet states in periodically driven quantum systems.
- Describe the basic aspects of the Floquet theory for isolated and open quantum systems.
- Discuss several examples of Floquet states, including ac Wannier–Stark effects and Floquet topological phases.
- Review experimental observations of Floquet states in solids and cold-atom systems.

Introduction

Driving quantum systems far from equilibrium provides various possibilities to control quantum states and realize new phases of matter that are otherwise inaccessible within thermal equilibrium. The interest on nonequilibrium states in condensed matter physics has grown rapidly due to recent progress both in theories and experiments, the latter of which allow for real-time observation of driven quantum states in a fast time scale in solids as well as in artificial quantum systems. There are many ways to drive quantum systems, among which time-periodic driving generates characteristic (quasi)stationary states called Floquet states, which are often accompanied by quasiparticles dressed by external driving fields. Their physical properties, such as band mass, lifetime, topological nature, etc., deviate from those of equilibrium states, depending on the driving protocol. This opens up a new avenue to control macroscopic phases dynamically.

The term, “Floquet states,” originates from the Floquet theory for a set of ordinary differential equations of the type, $\dot{x}_m(t) = \sum_n C_{mn}(t)x_n(t)$, with $C_{mn}(t) = C_{mn}(t + T)$ being a periodic function with a period T , which dates back to the work of a mathematician, G. Floquet in 1883 (Floquet, 1883; Hill, 1886; Magnus and Winkler, 1966). According to the Floquet theory, there exists a solution in a form of $x_m(t) = e^{i\lambda t}u_m(t)$ with a complex number λ (characteristic exponent) and a periodic function $u_m(t) = u_m(t + T)$. The application of the theory to the time-dependent Schrödinger equation in quantum mechanics laid down the foundation for the theory of Floquet states in periodically driven quantum systems (Shirley, 1965; Sambe, 1973; Grifoni and Hänggi, 1998). The Floquet theory can be viewed as a temporal analog of the Bloch theory in solid state physics, which serves as a fundamental framework to treat electronic states in a spatially periodic crystal structure.

Periodically driven quantum systems are typically classified into two types: one is the case of isolated quantum systems driven by time-periodic fields, whose time evolution is purely determined by the unitary dynamics. The other is the case of open quantum systems, that is, systems coupled to environment with dissipation. The dynamics are quite different between them (see Fig. 1). The former eventually reaches an infinite-temperature state in the long-time limit (Lazarides et al., 2014; D’Alessio and Rigol, 2014; Ponte et al., 2015a), since the energy is continuously supplied to the system by the periodic driving, which turns into heat in general (nonintegrable) systems. Before approaching the infinite-temperature state, the system may stay at an intermediate quasistationary

Fig. 1 Typical time evolution of an observable $\langle O(t) \rangle$ in (A) periodically driven isolated quantum systems and (B) periodically driven open quantum systems. The former reaches an infinite-temperature steady state through an intermediated quasistationary Floquet prethermal state, while the latter reaches a time-periodic nonequilibrium steady state (NESS).

state (called Floquet prethermalization) for a certain time scale, which becomes exponentially long when the driving frequency is relatively high as compared to the system's energy scale (Mori et al., 2016; Kuwahara et al., 2016; Abanin et al., 2017; Mori et al., 2018). The latter, on the other hand, may arrive at a time-periodic nonequilibrium steady state (NESS), in which the energy absorbed from the external field is balanced with that dissipating into environment (Tsuji et al., 2009; Oka and Aoki, 2009; Dehghani et al., 2014; Mikami et al., 2016; Shirai et al., 2016; Murakami et al., 2017; Ikeda and Sato, 2020).

In addition to these typical cases, nontrivial time-periodic stationary states are known to emerge in driven many-body localized systems, where heating is avoided without coupling to environment due to the effect of strong disorder (Ponte et al., 2015b; Lazarides et al., 2015; Abanin et al., 2016) and the emergence of approximately conserved charges (Das, 2010; Haldar et al., 2018; Haldar and Das, 2022). Recent studies (Sacha, 2015; Khemani et al., 2016; Else et al., 2016; Yao et al., 2017; Moessner and Sondhi, 2017) have unveiled another possibility that time-periodic steady states in periodically driven quantum systems can possess a different periodicity than that of the driving field, which is referred to as a (discrete) time crystal in the sense that the discrete time translation symmetry is spontaneously broken (as in the space translation symmetry broken in a crystal). In this way, the landscape of stationary states in periodically driven quantum systems is widely broadened, and many different types of quasiparticles can be found there.

Floquet theory

In quantum mechanics, the Floquet theory plays a fundamental role in describing Floquet states that emerge under an application of time-periodic driving fields. In the case of isolated quantum systems, the time evolution is determined by the time-dependent Schrödinger equation,

$$i \frac{d}{dt} |\psi(t)\rangle = H(t) |\psi(t)\rangle, \quad (1)$$

where $|\psi(t)\rangle$ and $H(t)$ are the system's wavefunction and hermitian Hamiltonian, respectively, and we set $\hbar = 1$ throughout the article. The Hamiltonian is assumed to have time periodicity, $H(t+T) = H(t)$, with a period T (and frequency $\omega = 2\pi/T$). The formal solution to the Schrödinger equation (1) is written as $|\psi(t)\rangle = U(t, t_0) |\psi(t_0)\rangle$ ($t \geq t_0$), where $U(t, t_0)$ is the unitary evolution operator defined by

$$U(t, t_0) := \mathcal{T} \exp \left(-i \int_{t_0}^t d\bar{t} H(\bar{t}) \right) \quad (2)$$

with $\mathcal{T}$ representing the time-ordered product.

The spirit of the Floquet theory lies in the idea of decomposing the overall dynamics into stroboscopic evolution (i.e., a sequence of snapshots at times $s \rightarrow s+T \rightarrow s+2T \rightarrow \dots$) and micromotion (i.e., $s \rightarrow s+t$ ($0 \leq t < T$)). The former contains information about long-time and time-averaged dynamics, while the latter includes information on fast dynamics in a short-time scale. To describe stroboscopic dynamics, it is convenient to consider time evolution by one cycle, starting from time s ,

$$U(s+T, s) =: e^{-iH_F(s)T}, \quad (3)$$

where we define a hermitian operator $H_F(s)$ as an effective 'static' Hamiltonian that describes time evolution over one period. Alternatively, one can write $H_F(s) = iT^{-1} \log U(s+T, s)$. The eigenvalues of $H_F(s)$ are determined only up to modulo $\omega = 2\pi/T$. Once $H_F(s)$ is known, stroboscopic dynamics from s to $s+nT$ ($n = 1, 2, 3, \dots$) is given by $U(s+nT, s) = e^{-inH_F(s)T}$. In general, however, $H_F(s)$ is a highly nonlocal and complicated many-body operator.

For general time evolution, one can rewrite the unitary operator $U(t, t_0)$ (2) as

$$U(t, t_0) = U(t, s) e^{i(t-s)H_F(s)} e^{-i(t-t_0)H_F(s)} e^{-i(t_0-s)H_F(s)} U(s, t_0) \quad (4)$$

with a free parameter s . The above equation indicates how $U(t, t_0)$ differs from $e^{-i(t-t_0)H_F(s)}$. If $t_0 = s$ and $t = s + T$, the two are identical, while in other cases they are not in general. The discrepancy between $U(t, t_0)$ and $e^{-i(t-t_0)H_F(s)}$ is characterized by a unitary operator

$$P_s(t) := U(t, s)e^{i(t-s)H_F(s)}, \quad (5)$$

which is time periodic ($P_s(t + T) = P_s(t)$) by construction. Using $P_s(t)$ (5), one can express the time-evolution operator as

$$U(t, t_0) = P_s(t)e^{-i(t-t_0)H_F(s)}P_s(t_0)^{-1}. \quad (6)$$

Now we are in a position to state Floquet's theorem in the present context.

Floquet's theorem—Given a time-periodic Hamiltonian $H(t) = H(t + T)$ and the corresponding unitary evolution operator $U(t, t_0)$ (2), there exist a time-independent hermitian operator H_F and a time-periodic unitary operator $P(t) = P(t + T)$ such that

$$U(t, t_0) = P(t)e^{-i(t-t_0)H_F}P(t_0)^{-1}. \quad (7)$$

Since we have already given an example of explicit constructions of the operators H_F and $P(t)$ in the above (Eqs. 3 and 5), the proof of the theorem has been completed. The operator H_F and its eigenvalues are often referred to as Floquet Hamiltonian and quasienergies, respectively. If one substitutes Eq. (7) in the equation of motion, $i\partial_t U(t, t_0) = H(t)U(t, t_0)$, one obtains a relation between H_F and $P(t)$,

$$H_F = P(t)^{-1}(H(t) - i\partial_t)P(t). \quad (8)$$

The choice of the combination $\{H_F, P(t)\}$ is not unique. This can be seen in the previous example, where $H_F(s)$ (3) and $P_s(t)$ (5) depend on the free parameter s . On the other hand, $\{H_F, P(t)\}$ does not necessarily correspond to $\{H_F(s), P_s(t)\}$ for certain s .

Although the combination $\{H_F, P(t)\}$ is not unique, the eigenvalues of H_F are unique (up to mod ω). Suppose that there exist two pairs, $\{H_F, P(t)\}$ and $\{\tilde{H}_F, \tilde{P}(t)\}$, that satisfy Eq. (7). By defining a unitary operator $V(t_0) := P(t_0)^{-1}\tilde{P}(t_0)$, one can see that they are related through

$$e^{-i\tilde{H}_F T} = V(t_0)^{-1}e^{-iH_F T}V(t_0), \quad (9)$$

$$\tilde{P}(t) = P(t)e^{-i(t-t_0)H_F}V(t_0)e^{i(t-t_0)\tilde{H}_F}. \quad (10)$$

These are a kind of “gauge transformations” that characterize nonuniqueness of $\{H_F, P(t)\}$. Note that $e^{-i\tilde{H}_F T}$ is related to $e^{-iH_F T}$ through the unitary transformation; hence, the eigenvalues of H_F and $\tilde{H}_F$ are identical up to mod ω (except for the difference in order). It is always possible to choose a gauge in such a way that $P(t_0) = I$ (the identity operator). If $P(t_0) \neq I$, one can perform a gauge transformation with $V(t_0) = P(t_0)^{-1}$, which gives $\tilde{P}(t_0) = I$. In this particular gauge, the unitary operator is simplified to $U(t, t_0) = P(t)e^{-i(t-t_0)H_F}$.

The wavefunction evolves, according to Floquet's theorem (7), as $|\psi(t)\rangle = P(t)e^{-i(t-t_0)H_F}P(t_0)^{-1}|\psi(t_0)\rangle$. If $P(t_0)^{-1}|\psi(t_0)\rangle$ is an eigenstate (say $|\psi_\alpha\rangle$) of H_F (with an eigenvalue ε_α), the wavefunction takes a form of

$$|\psi(t)\rangle = e^{-i\varepsilon_\alpha(t-t_0)}|u_\alpha(t)\rangle \quad (11)$$

with $|u_\alpha(t)\rangle := P(t)|\psi_\alpha\rangle$, which is time periodic, $|u_\alpha(t + T)\rangle = |u_\alpha(t)\rangle$. Thus, the wavefunction is decomposed into the phase factor and the time-periodic part in Eq. (11). This is analogous to the well-known Bloch's theorem for spatially periodic systems in solid-state physics, in which the Bloch wavefunction has a form of the product of a plane wave and a spatially periodic function (see Table 1 for comparison).

If $P(t_0)^{-1}|\psi(t_0)\rangle$ is not an eigenstate of H_F , one can still expand it in the complete eigenbasis of the hermitian operator H_F , $\{|\psi_\alpha\rangle\}_\alpha$, as

$$P(t_0)^{-1}|\psi(t_0)\rangle = \sum_\alpha c_\alpha |\psi_\alpha\rangle. \quad (12)$$

Then the wavefunction at time t is given by

Table 1 Comparison between Bloch's theorem for spatially periodic systems and Floquet's theorem for time-periodic systems.

	<i>Bloch</i>	<i>Floquet</i>
Hamiltonian	$H(\mathbf{r} + \mathbf{R}) = H(\mathbf{r})$	$H(t + T) = H(t)$
wavefunction	$ \psi_{\mathbf{k}}(\mathbf{r})\rangle = e^{i\mathbf{k}\cdot\mathbf{r}} u_{\mathbf{k}}(\mathbf{r})\rangle$, $ u_{\mathbf{k}}(\mathbf{r} + \mathbf{R})\rangle = u_{\mathbf{k}}(\mathbf{r})\rangle$ (crystal momentum $\mathbf{k}$)	$ \psi_\alpha(t)\rangle = e^{-i\varepsilon_\alpha t} u_\alpha(t)\rangle$, $ u_\alpha(t + T)\rangle = u_\alpha(t)\rangle$ (quasienergy ε_α)
Brillouin zone	$-\frac{\pi}{a} \leq \mathbf{k}_i < \frac{\pi}{a}$	$-\frac{\omega}{2} \leq \varepsilon_\alpha < \frac{\omega}{2}$

The Brillouin zone in momentum space is shown for a simple cubic lattice with a lattice constant a as an example.

$$|\psi(t)\rangle = \sum_{\alpha} c_{\alpha} e^{-i\varepsilon_{\alpha}(t-t_0)} |u_{\alpha}(t)\rangle, \quad (13)$$

where c_{α} is a time-independent coefficient. Again, the wavefunction is expressed as a combination of the phase factors and the time-periodic functions $|u_{\alpha}(t)\rangle$.

An observable $\langle O(t) \rangle = \langle \psi(t) | O | \psi(t) \rangle$ is not necessarily time periodic due to the presence of off-diagonal terms in the Floquet eigenbasis, $e^{i(\varepsilon_{\alpha}-\varepsilon_{\beta})(t-t_0)} \langle u_{\alpha}(t) | O | u_{\beta}(t) \rangle$ ($\alpha \neq \beta$). However, there are various situations where the contributions of the off-diagonal terms are suppressed, such as Floquet prethermalized states in an isolated system and NESS in open systems (Fig. 1). In those cases, time evolution of observables becomes periodic with the same periodicity as the driving field. An important exception is a discrete time crystal (Khemani et al., 2016; Sacha, 2015; Else et al., 2016; Yao et al., 2017; Moessner and Sondhi, 2017), where observables become time periodic but its periodicity is integer multiples of that of the driving field.

One can look at Floquet's theorem from another point of view, which is even closer to that of solid-state physics, that is, the band picture. By substituting the Floquet wavefunction (11) into the time-dependent Schrödinger equation (1), one obtains $i \frac{d}{dt} |u_{\alpha}(t)\rangle + \varepsilon_{\alpha} |u_{\alpha}(t)\rangle = H(t) |u_{\alpha}(t)\rangle$. Since $|u_{\alpha}(t)\rangle$ and $H(t)$ are both periodic in time, one can Fourier transform them into Fourier modes,

$$H_{mn} := T^{-1} \int_0^T dt e^{i(m-n)\omega t} H(t), \quad (14)$$

$$|u_{\alpha}^n\rangle := T^{-1} \int_0^T dt e^{in\omega t} |u_{\alpha}(t)\rangle. \quad (15)$$

Since H_{mn} only depends on $m - n$, one can also use a shorthand notation of $H_{m-n} := H_{mn}$. After that, the time-dependent Schrödinger equation turns into a seemingly time-independent equation,

$$\sum_n (\mathcal{H}_F)_{mn} |u_{\alpha}^n\rangle = \varepsilon_{\alpha} |u_{\alpha}^m\rangle, \quad (16)$$

$$(\mathcal{H}_F)_{mn} := H_{mn} - m\omega \delta_{mn}. \quad (17)$$

Here comes an idea of extending the Hilbert space in order to interpret Eq. (16) as an eigenvalue problem. Let $\mathbb{H}$ be the Hilbert space of the system, and let $\mathbb{T}$ be a vector space spanned by Fourier modes of time-periodic functions with the period T . For example, a periodic function $f(t) = f(t + T)$ is Fourier transformed as $f(t) = \sum_n f_n e^{-in\omega t}$. Then a vector $(\dots, f_{-2}, f_{-1}, f_0, f_1, f_2, \dots)$, whose elements are composed of Fourier coefficients, belongs to $\mathbb{T}$. Eq. (16) can be viewed as an eigenvalue equation in the extended Hilbert space $\mathbb{H} \otimes \mathbb{T}$ (Sambe space (Sambe, 1973)).

The set $\{\varepsilon_{\alpha}\}_{\alpha}$ has been defined as the eigenvalues of H_F acting on $\mathbb{H}$, while in Eq. (16) they appear as the eigenvalues of $\mathcal{H}_F$ acting on $\mathbb{H} \otimes \mathbb{T}$. Since the dimensions of $\mathbb{H}$ and $\mathbb{H} \otimes \mathbb{T}$ are different, there must be missing eigenvalues of $\mathcal{H}_F$, which can be found if one notices the fact that a vector $|u_{\alpha}^{n-l}\rangle$ shifted from $|u_{\alpha}^n\rangle$ by l components ($l = 0, \pm 1, \pm 2, \dots$) is also an eigenstate of $\mathcal{H}_F$ with an eigenvalue $\varepsilon_{\alpha} - l\omega$. This means that $\{|u_{\alpha}^{n-l}\rangle\}_{\alpha,l}$ consists of a complete set of the eigenstates in $\mathbb{H} \otimes \mathbb{T}$. The spectrum of the corresponding eigenvalues $\{\varepsilon_{\alpha} - l\omega\}_{\alpha,l}$ shows a periodic structure in energy space, in much the same way as the band structure shows a periodic pattern in momentum space for spatially periodic systems. In particular, one can restrict the energy space within $-\frac{\omega}{2} \leq \varepsilon_{\alpha} < \frac{\omega}{2}$ (the Floquet Brillouin zone) by shifting quasienergies by integer multiples of ω in order to represent quasienergies without mod ω redundancies.

Thus, H_F and $\mathcal{H}_F$ share the same eigenvalues up to mod ω . As we have mentioned, H_F is a complicated nonlocal many-body operator that is expected to be difficult to evaluate directly, while $\mathcal{H}_F$ is usually a well-behaved local few-body operator. On the other hand, the latter is acting on the extended space $\mathbb{H} \otimes \mathbb{T}$, whose dimension is infinitely larger than $\mathbb{H}$. In practice, one can truncate the Fourier space $\mathbb{T}$ to finite dimensions as an approximation; Off-diagonal elements, $(\mathcal{H}_F)_{mn}$, physically correspond to $m - n$ photon absorption/emission processes, which would be suppressed when $|m - n| \gg 1$ if the drive strength is not too strong.

Examples

As an example, let us consider a single-band system of noninteracting electrons driven by a time-periodic field described by the Hamiltonian

$$H(t) = \sum_{\mathbf{k}} \varepsilon_{\mathbf{k}}(t) c_{\mathbf{k}}^{\dagger} c_{\mathbf{k}}, \quad (18)$$

where $c_{\mathbf{k}}^{\dagger}$ is a creation operator of electrons with momentum $\mathbf{k}$, and $\varepsilon_{\mathbf{k}}(t) = \varepsilon_{\mathbf{k}}(t + T)$ is a band dispersion including the coupling to a time-periodic field. The eigenvalues (quasienergies) of the corresponding $\mathcal{H}_F$ (17) are given by $T^{-1} \int_0^T dt \varepsilon_{\mathbf{k}}(t) + n\omega$ ($n = 0, \pm 1, \pm 2, \dots$) (Tsuji et al., 2008), that is, the time-averaged dispersion shifted by integer multiples of the drive frequency ω . One can confirm that these are also eigenvalues of H_F (7) since the time evolution operator is given by $U(t, t_0) = e^{-i \int_{t_0}^t ds \sum_{\mathbf{k}} \varepsilon_{\mathbf{k}}(s) c_{\mathbf{k}}^{\dagger} c_{\mathbf{k}}}$ which is free from the time-ordering operator due to $[H(t), H(t')] = 0$.

If the system is a one-dimensional lattice with a nearest-neighbor hopping with a dispersion $\varepsilon_k = -2J \cos k$ driven by an ac electric field with amplitude E (represented by a vector potential $A(t) = -E \sin \omega t / \omega$), the time average of the dispersion is given by $T^{-1} \int_0^T dt (-2J) \cos(k - A(t)) = -2J \mathcal{J}_0(E/\omega) \cos k$, where the hopping amplitude J is multiplied by $\mathcal{J}_0(E/\omega)$, the zeroth-order Bessel-function factor. In Fig. 2, we show the corresponding quasienergy spectrum. Due to the presence of the periodic drive, the hopping amplitude is effectively reduced ($|\mathcal{J}_0(E/\omega)| \leq 1$), and electrons become heavier. When the Bessel factor exactly vanishes ($\mathcal{J}_0(E/\omega) = 0$), electrons cannot hop to neighboring sites completely, resulting in dynamical localization (Dunlap and Kenkre, 1986; Holthaus, 1992). In the spectrum (Fig. 2), there are side-band structures (labeled by the Fourier mode index n) separated by ω from the neighboring bands, which is referred to as the dynamic Wannier–Stark ladder. These arise due to the consequence of virtual n -photon absorption/emission processes.

Another example is a model of Dirac electrons in two spatial dimensions driven by circularly polarized light (Oka and Aoki, 2009; Mikami et al., 2016). The Hamiltonian reads

$$H(t) = \sum_{k\alpha\beta} c_{k\alpha}^\dagger h_{k\alpha\beta}(t) c_{k\beta}, \quad (19)$$

$$h_{k\alpha\beta}(t) = (k_x - A_x(t))(\sigma_x)_{\alpha\beta} + (k_y - A_y(t))(\sigma_y)_{\alpha\beta}, \quad (20)$$

where $c_{k\alpha}^\dagger$ is a creation operator of electrons with two components (corresponding to two bands near the Fermi energy), $(A_x, A_y) = (A \cos \omega t, A \sin \omega t)$ is the vector potential for circularly polarized light, and σ_x and σ_y are Pauli matrices. In this system, circularly polarized light explicitly breaks time reversal symmetry.

In Fig. 3, a typical quasienergy spectrum is shown. When the driving field is absent, the spectrum consists of a Dirac cone (linear dispersion) without energy gap near $E = 0$. As one increases the amplitude of the electric field, there emerge energy gaps at the band crossing points, accompanied by sideband structures with energy spacing ω . Especially, at $k = 0$, the gap is given by $\Delta = \sqrt{\omega^2 + 4A^2} - \omega$ (Oka and Aoki, 2009). This phenomenon, light-induced gap opening in the quasienergy spectrum (accompanied by chiral edge modes), can be interpreted as a topological phase transition, since quasienergy bands are characterized by nonzero topological (Chern) numbers, similar to quantum Hall states in static systems. In this sense, the system is classified to a Floquet topological insulator (Oka and Aoki, 2009; Kitagawa et al., 2010, 2011; Lindner et al., 2011; Roy and Harper, 2017; Rudner and Lindner, 2020), a class of topological phases in periodically driven systems.

Fig. 2 The quasienergy spectrum of noninteracting electrons on a one-dimensional lattice driven by an ac electric field (solid curves). The dashed curve shows the original energy dispersion without the driving field.

Fig. 3 The quasienergy spectrum (solid curves) of Dirac electrons driven by circularly polarized light ($A = 1$, $\omega = 5$). The dashed lines with Fourier mode labels n show the spectrum without driving.

While the above example can be understood by mapping to the corresponding static model, there are several examples that show nontrivial topological phases that do not have equilibrium counterparts (Kitagawa et al., 2010, 2012; Rudner et al., 2013; Harper et al., 2020; Nakagawa et al., 2020a; Jangjan et al., 2022): Topologically protected chiral edge modes can appear even though all the bulk Floquet bands have vanishing Chern numbers. This is possible since in Floquet systems edge modes can go across the quasienergy $\varepsilon = \pm\pi/T$ (“anomalous π modes”) and wind around the Floquet Brillouin zone in the frequency domain. In this case, the system is called an anomalous Floquet topological insulator.

High-frequency expansion

The approach of the Floquet theory becomes particularly effective when the drive frequency is higher than typical energy scales included in the original (undriven) Hamiltonian. Intuitively, when the frequency is sufficiently large, physical degrees of freedom in the system cannot follow rapid oscillations of the drive field. As a result, the effect of the drive is rounded in the time average, implying that the Floquet Hamiltonian H_F defined in Floquet’s theorem (7) is approximated to be the time average of the original Hamiltonian, $H_F \approx H_0 = T^{-1} \int_0^T dt H(t)$. This intuition is actually justified in the form of high-frequency expansions (or $1/\omega$ expansion), a typical one of which reads

$$H_F = H_0 + \sum_{n=1}^{\infty} \frac{[H_{-n}, H_n]}{n\omega} + \dots, \quad (21)$$

where “...” contains higher order terms in $1/\omega$. The second term on the right-hand side of Eq. (21) can be understood as a sum of second-order perturbation corrections for n -photon absorption/emission processes.

There are several ways to carry out such an expansion (e.g., Floquet-Magnus expansion (Fel’dman, 1984; Casas et al., 2001; Blanes et al., 2009; Mananga and Charpentier, 2011; Goldman and Dalibard, 2014), van Vleck perturbation theory (Eckardt and Anisimovas, 2015; Bukov et al., 2015), and Brillouin-Wigner perturbation theory (Mikami et al., 2016)), all of which are known to be equivalent to each other in the sense that they all give the same high-frequency expansion for the eigenvalues of H_F (up to mod ω). One can derive some of them, for example, by starting from Eq. (8), $H_F = e^{i\Lambda(t)}(H(t) - i\partial_t)e^{-i\Lambda(t)}$, where $\Lambda(t)$ is a hermitian operator defined by $P(t) =: e^{-i\Lambda(t)}$. This relation can be rewritten with an adjoint operator $\text{ad}_{\Lambda(t)}X := [\Lambda(t), X]$ as

$$\frac{d}{dt}\Lambda(t) = \sum_{n=0}^{\infty} \frac{B_n}{n!} (-i)^n (\text{ad}_{\Lambda(t)})^n [H(t) + (-1)^{n+1} H_F], \quad (22)$$

where B_n is the Bernoulli number. One can solve Eq. (22) order-by-order by expanding

$$\Lambda(t) = \sum_{k=1}^{\infty} \Lambda^{(k)}(t), \quad H_F = \sum_{k=0}^{\infty} H_F^{(k)}, \quad (23)$$

where one assigns an order 1 for $H(t)$, the order k for $\Lambda^{(k)}$, and the order $k+1$ for $H^{(k)}$. In this rule, the superscript (k) of $\Lambda^{(k)}$ and $H^{(k)}$ represents the order in $1/\omega$.

To determine the expansion, one needs to fix the gauge. For example, one can set $\Lambda(t_0) = 0$ at certain time t_0 , which generates the so-called Floquet-Magnus expansion. While the expansion can be uniquely determined, there remains a spurious dependence on t_0 that appears as a phase factor in the expansion. Another choice that is often employed is $\int_0^T dt \Lambda(t) = 0$, which corresponds to the van Vleck perturbation expansion (Eq. 21) that does not have explicit t_0 dependence. These two expansions are related through unitary transformation.

The high-frequency expansions are usually asymptotic expansions. That is, they do not converge in the ordinary sense but give good approximation if the infinite series are truncated at a certain finite order. In fact, there is a rigorous estimate for the error induced by such a truncation, which suggests that the truncated Floquet-Magnus expansion accurately describes time evolution of periodically driven quantum systems up to a time scale which is exponentially long as a function of drive frequency. As a result, there emerges an exponentially long-lived prethermal regime (Fig. 1A) at an early stage of periodic driving, where the system shows thermal behavior with respect to the effective Hamiltonian given by the truncated expansion.

As an example, let us apply the high-frequency expansion to a model of noninteracting electrons on a honeycomb lattice driven by circularly polarized light. The Hamiltonian is given by

$$H(t) = J \sum_{\langle jk \rangle} \left[\exp \left(-i \int_{R_k}^{R_j} A(t) \cdot dr \right) c_j^\dagger c_k + \text{h.c.} \right], \quad (24)$$

where $\langle jk \rangle$ denotes nearest-neighbor sites at positions R_j and R_k on the honeycomb lattice, and $A(t)$ represents a vector potential for circularly polarized light, which is included as a Peierls phase. In the high-frequency expansion (21), the corresponding effective Hamiltonian is given by (Mikami et al., 2016)

$$H_F = J_{\text{eff}} \sum_{\langle jk \rangle} (c_j^\dagger c_k + \text{h.c.}) + K_{\text{eff}} \sum_{\langle\langle jk \rangle\rangle} (i\tau_{j,k} c_j^\dagger c_k + \text{h.c.}) + O\left(\frac{1}{\omega^2}\right), \quad (25)$$

where $\langle\langle jk \rangle\rangle$ represents next-nearest-neighbor sites, $J_{\text{eff}} = J\mathcal{J}_0(A)$, $K_{\text{eff}} = -J^2/\omega \sum_{n \neq 0} \mathcal{J}_n(A)^2 \sin(2\pi n/3)/n$ ($\mathcal{J}_n(A)$ is the n th-order Bessel function), and $\tau_{j,k} = \pm 1$ represents the chirality of the hopping from k to j ($+$ ($-$) is assigned to the clockwise (counterclockwise) path on a hexagon).

In addition to the modulated nearest-neighbor hopping, there appear next-nearest-neighbor hoppings that are purely imaginary. The resulting Hamiltonian is equivalent to the Haldane model (Haldane, 1988), a tight-binding model on a honeycomb lattice with complex next-nearest-neighbor hoppings, which is known to be a model of quantum anomalous Hall states (Chern insulators). Thus, one can understand that the system undergoes a topological phase transition induced by circularly polarized light. This is consistent with the result of the model of Dirac electrons treated in the previous section. As one reduces the drive frequency, higher order terms in the high-frequency expansion become relevant, and more complicated topological phases can be found with high Chern numbers (Mikami et al., 2016).

Periodically driven open quantum systems

In open quantum systems, the time evolution of the system is not simply given by the time-dependent Schrödinger equation (1) due to the effect of environment. Let the total Hamiltonian be given as $H = H_S + H_I + H_B$, where H_S is the system's Hamiltonian, H_I represents the interaction between the system and environment, and H_B is the Hamiltonian of environment (bath). The density matrix of the total system ρ evolves according to the von Neumann equation, $\frac{d}{dt}\rho = -i[H, \rho]$. What one is interested in here is the time evolution of the system's density matrix defined by $\rho_S = \text{tr}_B \rho$ (tr_B denotes the partial trace over environment's degrees of freedom).

One approach to describe the system's dynamics is to use a quantum Master equation, which is a quantum analog of Master equations in classical stochastic processes (Breuer and Petruccione, 2007). To derive the quantum Master equation, there are two basic assumptions: (i) Markovianity of system's time evolution (i.e., $\rho_S(t + \Delta t)$ is solely determined from $\rho_S(t)$) and (ii) absence of initial correlations between the system and environment (i.e., $\rho(0) = \rho_S(0) \otimes \rho_B(0)$). In this situation, if a map from arbitrary $\rho_S(0)$ to $\rho_S(t)$ is completely positive and trace preserving, $\rho_S(t)$ obeys the following form of the quantum Master equation (Gorini-Kossakowski-Sudarshan-Lindblad equation (Gorini et al., 1976; Lindblad, 1976)),

$$\frac{d}{dt}\rho_S = -i[H_S, \rho_S] + \sum_j \left(L_j \rho_S L_j^\dagger - \frac{1}{2} \{L_j^\dagger L_j, \rho_S\} \right), \quad (26)$$

with a certain set of operators $\{L_j\}$ called Lindblad operators (or jump operators). The second term on the right-hand side of Eq. (26) represents the effect of environment, giving nonunitary dynamics. If one defined a nonhermitian effective Hamiltonian, $H_{\text{eff}} := H_S - \frac{i}{2} \sum_j L_j^\dagger L_j$, Eq. (26) is rewritten as

$$\frac{d}{dt}\rho_S = -i(H_{\text{eff}}\rho_S - \rho_S H_{\text{eff}}^\dagger) + \sum_j L_j \rho_S L_j^\dagger. \quad (27)$$

The second term on the right-hand side of Eq. (27) represents quantum jump processes, in which the system's state discontinuously changes in a stochastic manner.

A microscopic justification of the quantum Master equation (26) often requires additional approximations. The conventional approach employs (i) the Born approximation which is valid for the weak coupling between the system and environment and (ii) the secular approximation (or the rotating-wave approximation) that can be justified when the inverse of the level spacing between the eigenvalues of H_S is much smaller than the relaxation time of the system. The latter condition does not usually hold for many-body systems since the level spacing becomes exponentially small as the system size increases. Nevertheless, the quantum Master equation has been used from a phenomenological point of view to describe the dynamics of open quantum many-body systems (Diehl et al., 2010; Prosen, 2011; Tindall et al., 2019; Nakagawa et al., 2020b; Yamamoto et al., 2021).

In the presence of periodic driving, the use of the quantum Master equation needs more careful derivation (Mori, 2023). Especially, if one is interested in nontrivial NESS, heating due to the periodic drive should be balanced with dissipation. The relaxation time then becomes comparable to the system's intrinsic time scale, which may invalidate the secular approximation. There has recently been a proposal for the derivation of quantum Master equations without relying on the secular approximation (or the rotating-wave approximation) (Nathan and Rudner, 2020, 2022). The underlying notion is that Markovianity is a property of the bath and the system-bath coupling solely, and should not depend on details of the energy level structure of the system. In fact, one can derive a Markovian quantum Master equation (called the 'universal Lindblad equation') when the correlation time of the bath is much shorter than the characteristic time scale of the system-bath interaction.

Another approach to driven open quantum systems is to use nonequilibrium Green's functions (Kadanoff and Baym, 1962; Keldysh, 1965). The advantage of this approach is that it does not necessarily rely on the Markov and secular approximations. On the other hand, since the approach is based on the Green's function formalism, one has to adopt certain diagrammatic techniques to treat many-body interactions.

One of the simplest models of environment for electrons is a free-fermion heat bath (Tsuji et al., 2009; Aoki et al., 2014), whose Hamiltonians are given by

$$H_B = \sum_{j,k} \varepsilon_k b_{j,k}^\dagger b_{j,k}, \quad (28)$$

$$H_I = \sum_{j,k} V_k (c_j^\dagger b_{j,k} + \text{h.c.}), \quad (29)$$

where $c_j^\dagger$ and $b_{j,k}^\dagger$ are creation operators of system's and bath's electrons at site j and mode k , respectively, ε_k is the energy of bath's electrons, and V_k is a coupling between system's and bath's electrons. The system's retarded, advanced, and Keldysh Green's functions are defined as

$$G_{ij}^R(t, t') = -i\theta(t - t') \langle \{c_i(t), c_j^\dagger(t')\} \rangle, \quad (30)$$

$$G_{ij}^A(t, t') = i\theta(t' - t) \langle \{c_i(t), c_j^\dagger(t')\} \rangle, \quad (31)$$

$$G_{ij}^K(t, t') = -i \langle [c_i(t), c_j^\dagger(t')] \rangle, \quad (32)$$

respectively ($\theta(t)$ is the step function). The retarded (and advanced) Green's function contains information about the single-particle spectrum of the system while the Keldysh one carries information about the occupation distribution of the spectrum.

Since the total Hamiltonian $H = H_S + H_I + H_B$ is quadratic in $b_{j,k}^\dagger$ and $b_{j,k}$, one can integrate out the bath's degrees of freedom analytically. As a result, the system's Green's function satisfies the following Dyson equation

$$\begin{pmatrix} G^R & G^K \\ 0 & G^A \end{pmatrix} = \left[\begin{pmatrix} G_0^R & G_0^K \\ 0 & G_0^A \end{pmatrix}^{-1} - \begin{pmatrix} \Sigma_b^R & \Sigma_b^K \\ 0 & \Sigma_b^A \end{pmatrix} - \begin{pmatrix} \Sigma^R & \Sigma^K \\ 0 & \Sigma^A \end{pmatrix} \right]^{-1}, \quad (33)$$

where G_0 is the system's noninteracting Green's function, Σ_b is the self-energy due to the coupling to the heat bath, and Σ is the system's self-energy. For the free-fermion bath, the retarded component of Σ_b is explicitly given in the frequency domain as

$$\Sigma_b^R(\nu) = \sum_k \frac{V_k^2}{\nu - \varepsilon_k + i\eta}, \quad (34)$$

where η is an infinitesimal positive constant. By using $1/(\nu + i\eta) = \mathcal{P}(1/\nu) - i\pi\delta(\nu)$ (with $\mathcal{P}$ being the principal value), one obtains the imaginary part of $\Sigma_b^R(\nu)$,

$$\Gamma(\nu) = \sum_k \pi V_k^2 \delta(\nu - \varepsilon_k), \quad (35)$$

which corresponds to the bath's spectral function. One often assumes a flat density of states for the bath, $\Gamma(\nu) = \Gamma$, as the simplest choice. The real part of $\Sigma_b^R(\nu)$ gives a potential shift, which can be renormalized into the chemical potential. The advanced component is simply the complex conjugate, $\Sigma_b^A(\nu) = \Sigma_b^R(\nu)^\dagger$. The Keldysh part of Σ_b is determined from the fluctuation-dissipation relation for the bath's Green's function, giving $\Sigma_b^K(\nu) = F(\nu)[\Sigma_b^R(\nu) - \Sigma_b^A(\nu)]$ with $F(\nu) = \tanh(\beta\nu/2)$ (β is the inverse temperature of the heat bath).

To summarize, the self-energy due to the coupling to the free-fermion bath takes a simple form

$$\begin{pmatrix} \Sigma_b^R(\nu) & \Sigma_b^K(\nu) \\ 0 & \Sigma_b^A(\nu) \end{pmatrix} = \begin{pmatrix} -i\Gamma & -2i\Gamma F(\nu) \\ 0 & i\Gamma \end{pmatrix}. \quad (36)$$

Although the free-fermion bath model looks somewhat artificial, it correctly reproduces the semiclassical result of Boltzmann's transport theory (Han, 2013; Aoki et al., 2014). In this context, the model can be viewed as a two-parameter phenomenology (the relaxation rate Γ and heat bath's temperature β^{-1}) to describe dissipation. One can also employ other models for a heat bath such as a model of phonons, but then the bath's degrees of freedom cannot be integrated out analytically, and one has to use certain approximations.

One can incorporate the effect of periodic driving in this approach. To this end, one assumes the existence of time-periodic NESS. Once the steady state is reached, the Green's function should satisfy the periodicity in two-time arguments, $G^\alpha(t, t') = G^\alpha(t + T, t' + T)$ ($\alpha = R, A, K$). This allows one to define the Floquet Green's function (Faisal, 1989; Martinez, 2003, 2005; Tsuji et al., 2008; Aoki et al., 2014; Liu et al., 2017),

$$G_{mn}^\alpha(\nu) := \frac{1}{T} \int_0^T ds \int_{-\infty}^{\infty} dt e^{i(m-n)\omega s + i\nu t} G^\alpha\left(s + \frac{t}{2}, s - \frac{t}{2}\right), \quad (37)$$

which takes a matrix form with indices m and n being the labels of Fourier modes as used in Eq. (14). The Dyson equation maintains the form of Eq. (33) with all the Green's functions and self-energies written in the above matrix form with the inverse interpreted as the matrix inverse. The Floquet matrix form of Σ_b reads $\Sigma_{b,mn}^R(\nu) = -i\Gamma\delta_{mn}$ and $\Sigma_{b,mn}^K(\nu) = -2i\Gamma F(\beta(\nu + n\omega)/2)\delta_{mn}$.

Provided that the self-energy from the system's interaction is given, the Green's function in the time-periodic NESS is determined from the Dyson equation (33). This part requires a (diagrammatic) solver for quantum many-body problems. One such approach is

Fig. 4 (A) The single-particle spectrum $A(v, k)$ of the ac-field-driven Falicov–Kimball model calculated from the Floquet DMFT. (B) The corresponding schematic band structure of the ac-field-driven Mott insulator with the drive frequency ω . The upper and lower Hubbard bands (UHB and LHB) are shown by *solid curves*, and the accompanied Floquet sidebands are shown by *dashed curves*. (Adapted from Aoki et al. (2014) Nonequilibrium dynamical mean-field theory and its applications. *Reviews of Modern Physics* 86: 779.)

the so-called Floquet dynamical mean-field theory (DMFT) (Tsuji et al., 2008, 2009; Aoki et al., 2014; Joura et al., 2008; Lubatsch and Kroha, 2009), which is a combined formulation of the Floquet theory and nonequilibrium DMFT (Freericks et al., 2006; Aoki et al., 2014). The latter solves nonequilibrium quantum many-body problems under the local approximation of the self-energy (Georges et al., 1996).

In Fig. 4, an example of the result of the Floquet DMFT is shown for the ac-field-driven Falicov–Kimball model (Tsuji et al., 2008, 2009; Aoki et al., 2014), which is a simple model of correlated electrons that shows a Mott insulator-to-metal transition in equilibrium (Freericks and Zlatić, 2003). There emerges an ac-field-induced midgap state between the upper and lower Hubbard bands as Floquet sidebands with an energy spacing ω . Due to this, the system turns from a Mott-insulating state to an ac-field-induced metallic state. This exemplifies a quantum many-body Floquet state.

The nonequilibrium Green’s function approach not only describes the single-particle properties but also characterizes two-particle ones such as response functions and transport coefficients. To obtain those quantities, one has to evaluate two-particle Green’s functions on top of the single-particle Green’s function. For example, the transport property of the ac-field-driven Falicov–Kimball model can be identified from the optical conductivity spectrum, which shows a Drude-like peak structure at low energy instead of a Mott gap, indicating that the system indeed becomes metallic due to the effect of the ac field (Tsuji et al., 2009).

Experimental observations

Floquet states have been experimentally observed in various systems. In solid-state materials, occupied single-particle spectra can be measured by angle-resolved photoemission spectroscopy (ARPES), which can map out the band structure of correlated electrons in energy and momentum spaces below the Fermi level. The technique can also be applied to study nonequilibrium states of electrons in solids, in which case pump and probe pulses are applied with a certain time delay in between (time-resolved ARPES). The former pulse is used to drive electrons out of equilibrium while the latter is used to generate photoelectrons. During irradiation of a pump pulse, the system can be approximately considered to be driven periodically in time if the pump pulse contains sufficiently large number of oscillation cycles. Thus, the time-resolved ARPES offers an opportunity to observe Floquet states for electron systems.

In Fig. 5, an example of time-resolved ARPES spectra is shown for a topological insulator Bi_2Se_3 driven by a circularly polarized laser (Wang et al., 2013). In topological insulators, there are topologically protected gapless surface states, which support an energy dispersion of Dirac cones. This is precisely the same situation as we see in Section “Examples”: Dirac electrons driven by circularly polarized light undergoes a transition to a Floquet topological insulator with a gap opening at the Dirac point. In the time-resolved ARPES experiment, the energy gap is observed to appear under the excitation of a circularly polarized laser. On top of that, Floquet sideband structures are observed with the energy spacing of the drive frequency in the ARPES spectra. These are consistent with the results of the Floquet theory (Oka and Aoki, 2009) (see, e.g., Fig. 3). The subsequent experiment has also demonstrated the transition from the Floquet states to Volkov states, that is, photon-dressed states of free electrons, by time-resolved ARPES (Mahmood et al., 2016).

When Dirac electrons are driven by circularly polarized light and turn to a Floquet topological insulator, the bands around the Dirac point can acquire nonzero Chern numbers. As a result, the system shows the anomalous Hall effect, that is, current flows perpendicular to the direction of an applied dc electric field without a magnetic field. If the distribution of the occupied states is not far from that of zero-temperature equilibrium states, the Hall conductance approaches the quantized value. The Hall conductance of Dirac electrons in a monolayer graphene induced by a circularly polarized laser has been measured experimentally, using an on-chip photoconductive switch device (McIver et al., 2020). The result shows that Floquet topological bands indeed generate the anomalous Hall effect, demonstrating characteristic features of Floquet topological states.

Fig. 5 Time-resolved ARPES spectra of surface states of a topological insulator Bi_2Se_3 under circularly polarized laser excitation along (A) k_x and (B) k_y directions. (C) and (D) are the corresponding spectra after subtracting the spectra at $t = -500$ fs. (Adapted from Wang et al. (2013) Observation of Floquet-Bloch States on the Surface of a Topological Insulator. *Science* 342: 453–457.)

Fig. 6 Effective hopping amplitude of Bose-Einstein condensed cold atoms in a periodically shaken optical lattice as a function of the amplitude A of the periodic drive. The *dashed curve* represents the Bessel function $J_0(A)$. (Adapted from Lignier et al. (2007) Dynamical Control of Matter-Wave Tunneling in Periodic Potentials. *Physical Review Letters* 99: 220403.)

In contrast to solid-state systems, artificial quantum systems provide high controllability and ideal clean situations to realize Floquet states. For example, cold atomic gases trapped in an optical lattice are well described by a lattice model of isolated quantum many-body systems. One can then drive the system by periodically shaking the optical lattice potential in real space (Eckardt, 2017), mimicking the effect of ac electric fields for electrons.

In Fig. 6, the experimentally measured effective hopping amplitude of Bose-Einstein condensates in a periodically shaken optical lattice is shown as a function of the amplitude A of the periodic drive (Lignier et al., 2007). As we see in Sections “Examples” and “High-frequency expansion,” the Floquet theory predicts that the hopping amplitude is renormalized by the Bessel factor as

$J_{\text{eff}} = J\mathcal{J}_0(A)$, which perfectly agrees with the experimental observation. Using this effect, one can effectively control the interaction strength with ac fields, inducing, for instance, a superfluid-to-Mott insulator transition in the Bose–Hubbard model (Eckardt et al., 2005). One can even reverse the sign of the hopping if $\mathcal{J}_0(A) < 0$, which can be used to realize frustrated classical spin systems (Struck et al., 2011) or to effectively convert the interaction from repulsive to attractive in the ac-field-driven Fermi–Hubbard model (Tsuji et al., 2011).

Periodic shaking of optical lattices has also been used to realize the Haldane model in fermionic cold-atom systems (Jotzu et al., 2014), where periodic circular shaking induces the Floquet topological insulator with complex hopping parameters on a honeycomb lattice as discussed above. The generated band gap is probed by momentum-resolved measurement of interband transitions. The effect of Berry curvature has been demonstrated by applying a constant force to atoms and finding an orthogonal drift, in the similar manner as the anomalous Hall effect. The induced Berry curvature has been reconstructed in the entire Brillouin zone experimentally (Fläschner et al., 2016).

Other physical systems that allow experimental observations of Floquet states include photonic systems (Kitagawa et al., 2012; Rechtsman et al., 2013; Maczewsky et al., 2017; Mukherjee et al., 2017; Ozawa et al., 2019), trapped ions (Kiefer et al., 2019), and superconducting qubits (Deng et al., 2015; Roushan et al., 2017).

Conclusion

Here we have reviewed basic aspects of Floquet states and their applications to various periodically driven quantum systems. It allows one to control phases of matter dynamically (“Floquet engineering” Bukov et al., 2015; Oka and Kitamura, 2019; Weitenberg and Simonet, 2021) that may not be realized in equilibrium. While our understanding of Floquet states has been deepened, the inherent potential of Floquet states has not been fully elaborated experimentally, especially in solid-state systems. This may be partly because (i) the required amplitude of electric fields is often large, (ii) one needs ultrafast time resolution to capture driven states during irradiation of a pump pulse, (iii) transitions to higher bands and modulation of the distribution may occur in real materials, (iv) heating will suppress quantum fluctuations, and (v) energy dissipation takes place in complicated ways.

While these will make it a great challenge to realize Floquet states in solids, they can also offer opportunities: The development of new materials and new devices will pave a way to explore the frontier of Floquet states. For example, a recent experiment has shown an ideal behavior of driven two-level systems with the scaling of the Bessel factor up to extremely high orders in a diamond nitrogen-vacancy center (Nishimura et al., 2022). If the interaction between the two-level systems can be implemented in those systems, it will provide an interesting playground of Floquet many-body states. Another opportunity is the effect of dissipation in open quantum systems, which can work in a favorable direction to realize (rather than suppress) new orders and new states of matter in quantum systems. For example, a two-body loss due to inelastic collisions in the Fermi–Hubbard model can effectively change the antiferromagnetic interaction to the ferromagnetic one (Nakagawa et al., 2020b), which has been recently observed in cold-atom systems (Honda et al., 2023). Finally, there has been an experimental progress in probing highly oscillating electronic states through high harmonic generation in solids (Chimire et al., 2011; Schubert et al., 2014; Luu et al., 2015; Vampa et al., 2015; Hohenleutner et al., 2015), which will be a useful key tool to study Floquet states in the future.

Abstract

Pump-probe spectroscopy based on femtosecond pulsed laser technology has been utilized to study the dynamic properties of materials out of equilibrium and to unveil the hidden properties in equilibrium. In particular, recent progress in terahertz time-domain spectroscopy and angle-resolved photoemission spectroscopy has enabled the time-resolved detection of low-energy electromagnetic responses and electron dispersion relations of the order of meV, at which many-body interactions associated with phase transitions and topologically non-trivial electron dynamics emerge. We describe the basics of pump-probe spectroscopy studies, which have contributed to the understanding of non-equilibrium properties in condensed matter physics.

Key points

- Importance of terahertz spectroscopy and angle-resolved photoemission spectroscopy for condensed matter physics.
- Time-resolved spectroscopy for ultrafast phenomena.
- Nonequilibrium physics induced by intense terahertz pulse.
- Combination of terahertz pulse and angle-resolved photoemission spectroscopy.

Introduction

The states of matter far away from thermal equilibrium, which vary rapidly over time, have been attracting growing interest in the field of modern condensed matter physics. Ultrafast time-resolved spectroscopy, also called pump-probe spectroscopy, is arguably the most important experimental technique for resolving the dynamical properties of nonequilibrium materials. In this technique, a strong light pulse drives a material into a non-equilibrium state (pump). A weaker light pulse is subsequently irradiated to measure the transient change in the properties of the material (probe). The time resolution is essentially determined by the duration of the pulses. For such applications, laser light has a great advantage because ultrashort pulses as short as or even shorter than 100 fs ($=10^{-13}$ s) can be easily generated by using mode-locked pulsed lasers and amplification systems.

Most of the existing laser light sources emit light in the near-infrared (NIR) or visible range. Accordingly, ultrafast time-resolved spectroscopy has been applied mainly in the study of semiconductors or molecules, in which the excitation of electrons occurs at the photon energy scale of 1 eV. However, the development of pulsed laser techniques has also realized efficient wavelength conversion via nonlinear light-matter interaction. Second-order nonlinear responses such as optical rectification or differential frequency generation enable the generation of terahertz (THz) pulses (0.1–10 THz in frequency, 30–3000 μm in wavelength). The THz frequency range corresponds to the intermediate region between electronics and photonics. The photon energy of THz pulses is on the order of meV, at which a variety of electromagnetic responses appear in condensed matter, as shown in Fig. 1. These responses include lattice vibrations (phonons), plasmons, cyclotron resonances, antiferromagnetic magnons, exciton inner transitions, superconducting gaps, and pseudogaps in high- T_c superconductors. In particular, the low-energy response of electrons at low temperatures is highly intriguing because it is sensitive to the physics near the Fermi surfaces, which reflects the many-body interactions associated with phase transitions and/or the topological nature of solid-state materials with relativistic fermions. Pump-probe spectroscopy using THz pulses is an important experimental tool for probing the low-energy responses in non-equilibrium materials.

Another important approach in pump-probe spectroscopy for the low-energy physics is the wavelength conversion through nonlinear optics into ultraviolet (10–400 nm) or soft X-ray (<10 nm) pulses by higher-order harmonic generation. Light with photon energies larger than the work function of solids can induce the photoelectric effect, in which excited electrons are ejected into the

Fig. 1 Varieties of electromagnetic responses in condensed matter.

Fig. 2 A typical setup of optical pump-THz probe spectroscopy. BS: Beam splitter, DS: Delay stage, C: Chopper, NLC: nonlinear crystal, OAP: Off-axis parabolic mirror, EOC: Electro-optic crystal, QWP: Quarter-half waveplate, WP: Wollaston Prism, BPD: Balanced photodiode.

vacuum while retaining the information of their energies, momenta, and spins. By directly capturing these electrons and resolving their energies and momenta, the dispersion relations of the electrons can be mapped with excellent energy and momentum resolutions. This technique is called angle-resolved photoemission spectroscopy (ARPES). By using a short-pulsed laser, time-resolved ARPES can also be realized and utilized to elucidate the electron dynamics in non-equilibrium condensed matters.

Here, we introduce pump-probe spectroscopy using THz pulses and ARPES as a probe and show how they have contributed to the recent progresses in non-equilibrium condensed matter physics. In addition, the remarkable progress in the techniques for generating intense THz pulses has enabled the utilization of THz pulses as a pump. The low-frequency intense driving fields have opened a new avenue for the study of nonequilibrium physics that was previously inaccessible with visible or near-infrared light.

Time-resolved THz-TDS

Fig. 2 shows a typical setup for optical pump and THz probe spectroscopy. The output of the pulsed laser is separated into the (i) pump pulse, (ii) generation of THz probe pulse, and (iii) gate pulse by beam samplers or splitters. The gate pulse is used to detect the THz electric field. A representative light source is the Ti:sapphire laser, in which a Ti-doped sapphire crystal excited by green light (approximately 500 nm) emits red light centered at 800 nm (1.55 eV photon energy). Depending on the crystal thickness, broadband light from 690 to 900 nm with a typical repetition rate of 80 MHz can be emitted to realize ultrashort laser pulses

with a duration of 15–100 fs. The pulsed output can be further amplified with the chirped pulse amplification scheme to obtain strong pulses >1 mJ with a typical repetition rate of 1 kHz. Recently, there is increasing demand for much higher repetition rates on the order of 100 kHz or 1 MHz for more efficient data accumulation. From this perspective, Yb-doped crystals are another candidate for lasing media. The crystals are excited by near-infrared laser diodes at approximately 980 nm and emit photons at approximately 1030 nm (1.2 eV photon energy). Because of the small Stokes shift, that is, small dissipation to the lattice, Yb-based crystals are robust for high-repetition lasing, while their pulse duration of 150–300 fs tends to be longer than that of Ti:sapphire lasers. The pump-probe spectroscopy system in Fig. 2 can be further extended into a variety of setups according to the required research purpose; for example, the pump pulse wavelength can be converted to a desired wavelength using an optical parametric amplifier.

Several techniques have been developed for efficient THz pulse generation. A well-known example is the photoconductive switch, or Auston switch, which comprises a semiconductor biased by gapped electrodes on its surface and a pulsed laser with photon energy larger than the band gap energy. When the gap between the electrodes is irradiated by a pulsed laser, photoexcited carriers are accelerated by the bias field to generate a transient current $j(t)$, which emits electromagnetic waves into free space. In the far-field, the field $E(t)$ is proportional to $dj(t)/dt$. The frequency of the electromagnetic field can reach the THz region when the carriers have short lifetimes of <1 ps. In addition to the external bias, the built-in electric field in heterostructures can also be a driving force of a transient current with laser pulse excitation. Another example is the photo-Dember effect in low-gap semiconductors such as InAs and InSb. Because of their large difference between the mobilities of photoexcited electrons and holes, photoexcitation induces a transient current perpendicularly to the surface, which acts as an efficient source of THz pulse emission.

Another approach for generating THz pulses is second-order nonlinear responses such as optical rectification or differential frequency generation in insulating nonlinear crystals. When a non-centrosymmetric crystal is irradiated by a short laser pulse with a photon energy smaller than the band gap energy, second-order polarization $P^{(2)} \propto \chi^{(2)} E_1 e^{i\omega_1 t} (E_2 e^{i\omega_2 t})^*$ can occur, where $E_j e^{i\omega_j t}$ is a component of the field that has frequency ω_j . This is called differential frequency generation. When $\omega_1 \sim \omega_2$, the generated polarization frequency $\omega_1 - \omega_2$ is very small and in the THz frequency range, and THz electromagnetic waves are emitted. In the far-field, the field $E(t)$ is proportional to $d^2 P(t)/dt^2$. Note that the second-order susceptibility $\chi^{(2)}$ can be nonzero only in the crystals without inversion symmetry. To generate THz pulses efficiently in thick crystals, the phase-matching condition between the laser and THz pulses must be satisfied in the crystals so that the THz waves generated during laser pulse propagation in the crystals can interfere constructively. ZnTe and GaP are typically used as nonlinear crystals in this regard. Nonlinear organic crystals such as DAST, DSTMS, and OH1 are also efficient THz emitters, although the absorptions in THz frequency somewhat distort the waveform.

The inverse processes to the photoconductive switch and the second-order nonlinear response are known as the photoconductive antenna and the electro-optic sampling, respectively, and can be utilized to detect THz pulses. The photoconductive antenna consists of a pair of gapped electrodes on a semiconductor surface to which THz and gate pulses are applied simultaneously. The carriers photoexcited by the gate pulse at the gap are accelerated in the direction of the THz field and can be detected as a current. In the electro-optic sampling, a THz pulse and a gate pulse are applied simultaneously to a nonlinear crystal that is transparent for the gate pulse. The THz electric field changes the refractive index of the nonlinear crystal, which is known as the Pockels effect. The induced birefringence can be detected as a change in the polarization of the gating pulses using the balanced detection. In both methods, the detected signals are proportional to the THz field including its sign. By changing the optical path lengths between the THz and gate pulses, the THz field waveform $E(t)$ can be obtained as a function of time.

The THz field waveform $E(t)$ can be transformed into $\sim E(\omega)$, the field in the frequency domain, using the Fourier analysis. This is called THz time-domain spectroscopy (THz-TDS). Importantly, because $\sim E(\omega)$ is a complex quantity, the amplitude and phase of the incident light at each frequency can be determined. By detecting light after transmission of or reflection from a sample, the amplitude and phase information of light can give the real and imaginary parts of refractive index of the sample $\sim n(\omega) = n(\omega) + i\kappa(\omega)$. The refractive index can be further converted to the dielectric function $\varepsilon(\omega) = \sqrt{\sim n(\omega)}$ in nonmagnetic media or the optical conductivity $\sigma(\omega) = i\varepsilon_0\omega(\varepsilon(\omega) - 1)$. By using THz-TDS, the response functions can be obtained directly as complex quantities without the Kramers-Kronig conversion. This is in a stark contrast to the conventional light detection by photodetectors, in which only the intensity of light is detected without the information of phase. Furthermore, because the THz pulse duration is as short as 1 ps, THz-TDS can be used as an ultrafast probe in the pump-probe spectroscopy shown in Fig. 2, in contrast to the Fourier-transform infrared spectroscopy.

As an example of optical pump-THz probe spectroscopy, we introduce a study of the s-wave superconductor NbN in Fig. 3a (Beck et al., 2011). Below T_c , a superconducting gap appears in the low-frequency absorption spectrum described by $\text{Re}[\sigma(\omega)]$. In contrast, $\text{Im}[\sigma(\omega)]$ shows a large inductive current proportional to n_s/ω , where n_s is the superfluid density. The full information of the complex response functions can be determined directly by THz-TDS, which can be used to track ultrafast change after the optical pump. The right panel in Fig. 2a shows a two-dimensional plot of the transient THz transmission spectra after optical excitation, indicating the suppression and recovery dynamics of the superconducting gap and the order parameter. After irradiation with 50-fs optical pump pulses at 1.55 eV, the superconducting gap energy denoted by the blue circles gradually decreased over a timescale of 10 ps. The 1.55-eV photons excite hot electrons with large excess energy, which emit a large number of phonons. Subsequently, the emitted phonons break Cooper pairs and excite high-density quasiparticles, which suppresses the gaps at the slower timescale. In the recovery dynamics, two quasiparticles recombine to form a Cooper pair, and they emit a phonon, but the phonon can excite quasiparticles again. Therefore, the recovery time of the superconducting gap is determined not only by the bare quasiparticle recombination time, but also by the decay time of phonons. These dynamics can be phenomenologically described using the Rothwarf-Taylor model.

Another example of optical pump-THz probe spectroscopy is the study for photoexcited carriers in semiconductors. Fig. 3b shows the transient THz conductivity and dielectric function spectra in photoexcited GaAs (Kaindl et al., 2009). The upper panels

are the results of the excitation at 100 meV above the band gap, showing the Drude response of free electron and holes. The lower panels are the resonant excitation of $1s$ excitons, showing the Lorentzian absorption of $1s$ - $2p$ inner transition. Electron-hole systems with negative and positive charges can exhibit a variety of phases such as ionized neutral plasmas, electron-hole bound states called excitons, electron-hole liquids/droplets, or quantum condensation into electron-hole BCS or exciton BECs depending on the temperature and carrier density as shown in Fig. 3c (Suzuki et al., 2009). The densities of the fermionic electron-hole gas and bosonic exciton pairs can be determined in the time-resolved THz spectroscopy, which unveils rich physics in the many-body system related with quantum condensations and the Mott transition/crossover.

The time-resolved THz spectroscopy has also been used to study a possible light-induced superconductivity in high- T_c cuprate superconductors (Fausti et al., 2011). Cuprate superconductors consist of two-dimensional metallic planes stacked along the c -axis with an intermediate insulating atomic layer. Below T_c three-dimensional superconducting transport is developed across the insulating layer through Josephson tunnelling, which manifests as a Josephson plasma resonance in the reflectivity spectra. Some cuprates show a transient Josephson plasma-like response after photoexcitation, suggesting the possibility of light-induced superconductivity far above T_c even at room temperature (Kaiser et al., 2014). Such light-induced superconductivity study was further extended to fullerene superconductors recently through strong excitation of optical phonons (Mitrano et al., 2016).

Time-resolved ARPES

Several kinds of light sources have been used as probe lights for time-resolved ARPES so far. These sources are, namely, vacuum ultraviolet (VUV) light (approximately 6 eV) generated by wavelength conversion using a solid-state nonlinear optical crystal (Ishida et al., 2014), extreme ultraviolet (EUV) light of approximately 20–60 eV generated by high harmonic generation (HHG) from a noble gas (Suzuki et al., 2021a, 2021b), synchrotron radiation (Yamamoto et al., 2013), and light from a free electron laser (Hellmann et al., 2012). Hereafter, we refer to EUV light generated by HHG as a HHG laser. Among the various types of light sources for time-resolved ARPES, the HHG laser has several advantages. The higher photon energy of the HHG laser compared to that of the VUV laser enables a wider energy and momentum space range to be probed. The pulse duration of the HHG laser generated from the fundamental laser of a regenerative amplifier system with a typical pulse duration of 30–100 fs is much shorter than that of synchrotron radiation, which is at best approximately 70 ps. The higher repetition rate (>1 kHz) compared to a free electron laser (typically several tens of hertz) prevents the occurrence of the space-charge effect, which induces energy broadening of photoelectrons due to Coulomb repulsion.

Fig. 4 shows the typical setup of an HHG laser-based time-resolved ARPES system (Suzuki et al., 2021a, 2021b). The output of the Ti:sapphire amplifier system, which has a central wavelength of 800 nm, average power of 6–7 W, pulse duration of 35 fs, and repetition rate of 1 kHz or 10 kHz, is first injected into a β -BaB₂O₄ (BBO) nonlinear optical crystal. The second harmonic is generated and the photon energy is doubled to 3.1 eV to improve the conversion efficiency of the HHG. The second harmonic is then focused on a gas cell filled with Ar to generate high harmonics. One of the harmonics, typically the seventh (21.7 eV) or ninth (27.9 eV) harmonic, is selected using a pair of SiC/Mg multilayer mirrors. The resulting photoelectrons are collected using a hemispherical electron analyzer. The typical time and energy resolutions are several tens of femtoseconds and one or two hundred meV, respectively.

The greatest advantage of utilizing time-resolved ARPES over other time-resolved techniques is the ability to observe electronic band structures. This advantage allows the insulating and metallic states to be clearly distinguished during photoinduced insulator-to-metal transitions and the Floquet states generated by the temporally periodic electric field of the laser to be observed. Here, we introduce a time-resolved ARPES study of Ta₂NiSe₅ as an example of the observation of photo-induced insulator-to-metal transition (Okazaki et al., 2018a, 2018b). Ta₂NiSe₅ is a unique candidate for excitonic insulators. An exciton is a bound state of electrons and holes caused by weakly screened Coulomb interaction. Excitonic insulators are insulators in which excitons are spontaneously condensed owing to the binding energy of the excitons exceeding the band gap of an insulator or the band overlap energy of a semimetal. A photoinduced insulator-to-metal transition was recently observed using HHG laser-based time-resolved ARPES. Fig. 5a and b show the energy-momentum (E - k) maps taken using time-resolved ARPES before and after the pump, respectively. The map before pumping shows the typical behavior of an excitonic insulator with a flat band below the Fermi level (E_F). In contrast, it can be recognized that the electron and hole bands indicated by red and blue lines cross E_F after the pump, suggesting that the system was transformed to a semimetallic state.

Fig. 4 Schematic illustration of the HHG-laser-based time-resolved ARPES system composed of a Ti:sapphire amplification system, HHG chamber, spectrometer, multi-layered mirror chamber, and hemispherical electron analyzer (Suzuki et al., 2021a, 2021b). BBO: β -BaB₂O₄, HHG: high harmonic generation.

Fig. 5 Time-resolved ARPES spectra of Ta₂NiSe₅ before and after pumping (Okazaki et al., 2018a, 2018b). (a) Energy-momentum ($E - k$) map before pumping, integrated in the time interval $[-0.29, 0]$ ps. (b) Corresponding map of the transient states, integrated in $[0, 1.2]$ ps. Red and blue parabolas indicate, respectively, the electron and hole bands crossing E_F in the non-equilibrium metallic state. These spectra were acquired with a pump fluence of 1.56 mJ/cm².

We introduce the observation of Floquet states and the development of frequency-domain ARPES as further examples of recent progress in time-resolved ARPES. Floquet states are states that are evenly spaced in energy generated by the temporally periodic electric field of a laser and can be regarded as the time analogue of Bloch states, which are periodic states in momentum space induced by a spatially periodic electric potential. Wang et al. first observed such states in the topological surface band of Bi₂Se₃ using a mid-infrared pulse with a lower energy than the band gap as the pump, which prevented the interband transitions of electrons (Wang et al., 2013). Another intriguing phenomenon observed by time-resolved ARPES is the excitation of coherent phonons (Okazaki et al., 2018a, 2018b; Suzuki et al., 2019; Suzuki et al., 2021a, 2021b). Coherent phonon excitations can also be observed by pump-probe optical spectroscopy, typically as temporally periodic reflectivity oscillations. By using time-resolved ARPES, the response of the electrons to excited coherent phonons through electron-phonon coupling can be observed as shifts in the band dispersions and/or modulations of the photoemission intensities. This enables deep insights into the electron-phonon coupling in the material to be obtained. Recently, a novel analysis method called frequency-domain angle-resolved photoemission spectroscopy (FDARPES) was developed and applied to the observation of the photo-induced excitonic insulator-to-semimetal transition in Ta₂NiSe₅ (Suzuki et al., 2021a, 2021b). An FDARPES image is a mapping of the coherent-phonon amplitude with respect to the energy and momentum of each frequency of coherent phonons. It can reveal the electron-phonon couplings of coherent phonons and their intriguing properties during the photo-induced phase transition.

Intense THz pulse-induced non-equilibrium phenomena

Recent remarkable progresses in intense THz pulse generation methods have allowed the low-frequency degrees of freedom in condensed matter to be resonantly or non-resonantly accessed by the strong driving forces. A well-known method for generating

intense THz pulses is the optical rectification in stoichiometric LiNbO_3 crystals (Hebling et al., 2008), which possess a high effective nonlinear coefficient as well as a high damage threshold with doping. To satisfy the phase-matching condition, the tilted-pulse front scheme was developed to compensate the large difference between the optical group velocity and THz phase velocity in the crystal. A strong electric field exceeding 1 MV/cm is available at the low frequency of 1 THz (Hirori et al., 2011). Organic nonlinear crystals with extremely large nonlinear coefficients, such as DAST or DSTMS, are also available for generating THz pulses with frequencies of a few THz through optical rectification (Hauri et al., 2011). The use of an infrared pulsed light source is desirable to avoid damage and to satisfy the phase-matching condition. Another representative example of intense THz pulse generation is emission from a two-color laser-induced air plasma (Cook and Hochstrasser, 2000). An extremely broadband frequency from 1 THz to mid- or near-infrared at 100 or 200 THz can be emitted depending on the laser pulse energy, focusing length, and pulse duration.

Here, we introduce some examples of pump-probe experiments that revealed intriguing nonequilibrium dynamics in condensed matter through the intense THz pulse excitation. Fig. 5a shows the results of THz pump-THz probe spectroscopy performed on the *s*-wave superconductor NbN (Matsunaga et al., 2013). The signal corresponds to a decrease in the superconducting gap and order parameter by the THz pump. In contrast to the optical pump in Fig. 2a, the superconducting gap suddenly decreases because the THz pump directly excites quasiparticles at the bottom of the superconducting gap without providing excess energy, which prevents the heating of the lattice and lead to a nonadiabatic perturbation to the superconducting phase. After the sudden quenching, the order parameter oscillates, as shown in Fig. 5a. This is the collective oscillation mode of the order parameter amplitude, which is associated with spontaneous symmetry breaking and recently called the Higgs mode because of its close analogy with the Higgs boson in elementary particle physics. Fig. 5b shows another example of the observation of the Higgs mode in THz pump-THz probe spectroscopy during THz pump irradiation with a frequency below the superconducting gap (Matsunaga et al., 2014). Although the Higgs mode is not directly coupled to light in the linear response regime, it can be resonantly excited by intense THz waves in the nonlinear response regime. The order parameter oscillation induced during the pump pulse irradiation can also be observed through efficient third-order harmonic generation.

The intense THz electromagnetic fields can also be used to drive the spin system. Because spin precession motion occurs in the THz frequency range in antiferromagnets, ultrafast control of the spin order is highly demanded for applications in next-generation fast spintronics. Fig. 6c shows the magnetization dynamics of spins in the antiferromagnetic dielectric HoFeO_3 (Mukai et al., 2016). The magnetic field in the intense THz pulse can nonlinearly drive antiferromagnetic spin motion and induces a large change of 40% in the spontaneous magnetization. In a specific material, spin motion can also be induced by the electric field component. The intense THz electric field abruptly changes the magnetic anisotropy in the antiferromagnet TmFeO_3 and induces large-amplitude spin motion at 83 K, leading to all-optical spin switching (Schlauderer et al., 2019).

The combination of an intense THz pump pulse and ARPES is also a recent intriguing subject in non-equilibrium physics. Fig. 6d shows the results of time-resolved ARPES on the surface Dirac state of the topological insulator Bi_2Te_3 under irradiation by a strong THz field with sub-cycle time resolution (Reimann et al., 2018). The acceleration of the Dirac fermions into ballistic transport by the THz field was directly visualized as a significant asymmetric redistribution of electrons in the momentum space. The acceleration of electrons across the Dirac node was accompanied by a sudden flip in the sign of the electron group velocity that led to extremely efficient THz harmonic generation, which was also demonstrated recently (Cheng et al., 2020).

Conclusion

In this article, we focused on pump-probe spectroscopy studies using THz pulses and ARPES, which are important for the study of low-energy physics in nonequilibrium condensed matter. The disadvantage of detecting only the low-energy response may become evident when the spot size of the far-field focusing is too large for a tiny sample and the time resolution is limited. However, by using on-chip generation and detection of sub-THz currents, the observation of light-induced anomalous THz Hall conductivity was recently realized in a tiny flake of exfoliated graphene under circularly polarised light, which revealed a phase transition to a Floquet topological insulator (McIver et al., 2020). Other approaches using mid-infrared, near-infrared, visible, ultraviolet, or X-ray/attosecond pulses are also very important for tracking ultrafast dynamics with a better time resolution. Phase-stable light sources are now available at mid-infrared, near-infrared, and visible frequencies. Pump-probe spectroscopy using light waves with sub-cycle resolution is attracting growing interest and opening up the new research field of petahertz electronics.

Abstract

Numerical simulations play an important role in theoretical investigations of nonequilibrium phenomena in correlated many-body systems. This overview focuses on lattice problems, such as the Hubbard model and its extensions. These models are relevant in the context of pump-probe experiments on solids, and for nonequilibrium studies of cold atoms in an optical lattice. The numerical approaches will be classified into (i) wave-function based methods, which may be used, for example, to obtain exact solutions for the dynamics of small systems, (ii) density-functional based methods, whose extension to strongly correlated systems is still under development, and (iii) nonequilibrium Green's function based methods, which include perturbative approaches for moderately correlated lattice problems, and dynamical mean field theory (DMFT) based methods which also provide access to the nonequilibrium properties of strongly correlated systems.

Introduction

Numerical simulations play an important role in theoretical investigations of nonequilibrium phenomena in correlated many-body systems. This overview focuses on lattice problems, such as the Hubbard model and its extensions. These models are relevant in the context of pump-probe experiments on solids (Giannetti et al., 2016), and for nonequilibrium studies of cold atoms in an optical lattice (Aoki et al., 2014). The numerical approaches will be classified into (i) wave-function based methods, which may be used, for example, to obtain exact solutions for the dynamics of small systems, (ii) density-functional based methods, whose extension to strongly correlated systems is still under development, and (iii) nonequilibrium Green's function based methods, which include perturbative approaches for moderately correlated lattice problems, and dynamical mean field theory (DMFT) based methods which also provide access to the nonequilibrium properties of strongly correlated systems.

Although the methods are applicable to a broad range of systems, most of the following discussions consider a Hubbard model with local interaction U (Gutzwiller, 1963), or a U - V Hubbard model with an additional nonlocal density-density interaction V . The Hamiltonian of the latter model is

$$H(t) = -t_{\text{hop}}(t) \sum_{\langle i,j \rangle \sigma} \left(c_{i\sigma}^\dagger c_{j\sigma} + \text{h.c.} \right) + U(t) \sum_i n_{i\uparrow} n_{i\downarrow} + V(t) \sum_{\langle i,j \rangle} n_i n_j - \mu \sum_i n_i, \quad (1)$$

where $c_{i\sigma}^\dagger$ is the creation operator for an electron with spin σ on site i , $n_{i\sigma} = c_{i\sigma}^\dagger c_{i\sigma}$ measures the spin-density on site i , $n_i = n_{i\uparrow} + n_{i\downarrow}$ is the total electron density on site i , t_{hop} represents the nearest-neighbor hopping amplitude and μ is the chemical potential. In a general nonequilibrium set-up, the parameters of the model can depend on time t . A time-dependent (complex) hopping term appears for example if an electric field acts on the system in a gauge with pure vector potential (Aoki et al., 2014). In the following, $\hbar$ and the electron charge are set to unity.

Wave-function based methods

Exact diagonalization

The time evolution of small systems, e.g., Hubbard clusters or chains with up to 20 sites, can be calculated using the time-dependent Lanczos method (Park and Light, 1986). Starting from an initial state described by $|\psi(0)\rangle$, the solution of the time-dependent Schrödinger equation $i\partial_t|\psi(t)\rangle = H(t)|\psi(t)\rangle$ yields the state at some later time t . In practice, the time propagation is split into small steps δt , such that $|\psi(t + \delta t)\rangle \approx e^{-iH(t)\delta t}|\psi(t)\rangle$. Expansion of the time-evolution operator into a power series,

$$e^{-iH(t)\delta t}|\psi(t)\rangle \approx \sum_{n=0}^{p-1} \frac{(-i\delta t H(t))^n}{n!} |\psi(t)\rangle, \quad (2)$$

yields p independent vectors $\{H(t)^n|\psi(t)\rangle, n=0, \dots, p-1\}$, which define the so-called Krylov space. The Lanczos algorithm (Lanczos, 1950), starting from $|\phi_0\rangle = |\psi(t)\rangle$, generates an orthogonal basis of p vectors $|\phi_n\rangle$, which spans the same Krylov space, and in which the Hamiltonian $H(t)$ becomes a tridiagonal matrix. This tridiagonal matrix is small (p is typically of $\mathcal{O}(10)$) and easily diagonalized using standard numerical techniques, which yields the eigenvectors $|\psi_l\rangle$ and corresponding energy eigenvalues ε_l . In terms of these, the state vector at time $t + \delta t$ can be expressed as

$$|\psi(t + \delta t)\rangle \approx \sum_{l=0}^{p-1} e^{-i\varepsilon_l \delta t} |\psi_l\rangle \langle \psi_l | \psi(t) \rangle. \quad (3)$$

While this approximation preserves the normalization of $|\psi(t + \delta t)\rangle$ for arbitrary δt , the time step needs to be chosen small enough that $H(t)$ does not vary significantly within a given time step, and the Taylor expansion up to a given order $p-1$ provides a good approximation of the time evolution operator for a single time step.

Larger systems can in some cases be treated by defining a suitable “limited functional space” (Edwards and Miyazaki, 1987; Trugman, 1988). For a single hole in the antiferromagnetic t - J model, the procedure works as follows (Bonca et al., 2007). Starting from a Néel state with a single hole, $|\phi_k^{(0)}\rangle = c_k|\text{Néel}\rangle$, new states are constructed by the iterative application of hopping terms. Since each hopping flips a spin against the antiferromagnetic background, this procedure will create string states in dimension $d > 1$. To reduce the number of states thus generated, and to increase the number of spin-flips in the vicinity of the hole, one imposes a constraint on the maximum distance between spin-flips. The time-dependent Lanczos procedure described above can then be applied to the Hamiltonian restricted to the limited functional space. This approach is variational in the sense that increasing the limited functional space systematically improves the description of the single-hole states.

Given the state vector $|\psi(t)\rangle$, expectation values of observables such as the current $j_x = it_{\text{hop}} \sum_{(i,j)\sigma} R_{ij}^\dagger (c_{i\sigma}^\dagger c_{j\sigma} - \text{h.c.})$, with $R_{ij}^\dagger$ the α -component of the lattice vector $R_{ij} = R_i - R_j$, can be calculated directly. To measure the time-dependent optical conductivity, one has to apply a weak probe pulse. Assuming that the probe pulse is short and of Gaussian form, the optical conductivity $\text{Re } \sigma_{xx}(\omega, t) = \frac{1}{L\omega} \text{Re} \int_0^\infty e^{i(\omega+i\eta)s} \langle \psi(t) | [j_x(s), j_x] | \psi(t) \rangle ds$ (with L the number of lattice sites and $\omega > 0$) can be measured using the formula (Shinjo and Tohyama, 2017)

$$\text{Re } \sigma_{xx}(\omega, t) = \frac{1}{L\omega} \sum_{m,n} \frac{\eta}{(\omega + \varepsilon_m - \varepsilon_n)^2 + \eta^2} \times [\langle \psi(t) | m \rangle \langle m | j_x | n \rangle \langle n | j_x | \psi(t) \rangle - \langle \psi(t) | j_x | m \rangle \langle m | j_x | n \rangle \langle n | \psi(t) \rangle], \quad (4)$$

with $|m\rangle$ and $|n\rangle$ denoting the eigenstates of the Hamiltonian with energies $\varepsilon_m, \varepsilon_n$ and η a small positive number.

While the numerical effort in exact diagonalization calculations scales linearly with time, and long times are thus in principle accessible, the simulations of small systems are affected by finite-size effects such as artificial recurrences. Correlations spread with a characteristic light-cone velocity v_{lc} , so that artifacts due to finite-size effects can be expected for times $\gtrsim L/(2v_{lc})$, where L is the linear size of the system.

Time-dependent DMRG and iTEBD

In the density-matrix renormalization group (DMRG) method (White, 1992), the state-vector $|\psi\rangle$ is approximated by a matrix-product state (MPS) with finite bond dimension m :

$$|\psi\rangle \approx \sum_{\sigma_1 \dots \sigma_L} \text{Tr}[\mathcal{A}_1^{\sigma_1} \dots \mathcal{A}_L^{\sigma_L}] |\sigma_1 \dots \sigma_L\rangle, \quad (5)$$

where σ_i represents the local degrees of freedom at site i and $\mathcal{A}_i^{\sigma_i}$ is a $m \times m$ matrix (Cirac et al., 2021). Without any constraints on the bond dimension, the representation (5) becomes exact, but the required bond dimension in general scales exponentially with

system size. Compact representations are however possible for one dimensional systems with short-range interactions, which is why DMRG is mainly used to study such systems (Schollwöck, 2011).

Given a one-dimensional lattice problem, the truncation is implemented by decomposing the system into subsystems A and B , performing a Schmidt decomposition $|\psi\rangle = \sum_{\alpha=1}^s s_{\alpha} |\alpha\rangle_A |\alpha\rangle_B$ into a new product basis with a single index α , and keeping only the m largest Schmidt coefficients $|s_{\alpha}|$ in the sum: $|\psi\rangle \approx \sum_{\alpha=1}^m s_{\alpha} |\alpha\rangle_A |\alpha\rangle_B$, assuming the ordering $|s_1| \geq |s_2| \geq \dots \geq |s_s|$. Details of the implementation can be found in Schollwöck, 2011. The efficiency of the method depends on how fast the Schmidt coefficients decay, and the discarded weight $\delta = \sum_{\alpha=m+1}^s s_{\alpha}^2$ is a useful measure for the error incurred by the truncation.

Some intuitive understanding can be gained from the connection to the entanglement entropy, $S_{\text{vN}} = -\sum_{\alpha} s_{\alpha}^2 \log s_{\alpha}^2$, and the scaling of S_{vN} with system size. If an area law holds, $S_{\text{vN}} \propto L_A^{D-1}$, with L_A the linear size of subsystem A and D the dimension. In this case, for $D = 1$, one finds $S_{\text{vN}}(L_A) = \text{const}$ for large enough L_A and $m \lesssim \exp(S_{\text{vN}}(L_A))$ does not increase with system size. In $D = 2$, however, the bond dimension grows exponentially with the width of the system, even if an area law holds.

In the calculation of the real-time evolution (Daley et al., 2004; Vidal, 2004; White and Feiguin, 2004), $|\psi(t)\rangle = e^{-iHt}|\psi(t=0)\rangle$, one employs a time discretization into small time steps δt and a Suzuki Trotter decomposition of the Hamiltonian $H = \sum_i h_{i,i+1}$ to end up with a product of operators $e^{-ih_{i,i+1}\delta t}$, which act on just two neighboring $\mathcal{A}$ matrices in Eq. (5). Grouping the sites into sublattices A and B , the time evolution operator for a given time-step is factorized into a product of operators acting on AB bonds and BA bonds. For global quenches or electric field perturbations, $S_{\text{vN}} \propto t$, which means that the bond dimension m needed to keep the same accuracy grows exponentially with time. This typically limits the time-dependent DMRG calculations to $\mathcal{O}(10)$ inverse hopping times. The parameter δt is the second parameter affecting the accuracy of the simulation, but the effect of the time-discretization can be reduced by implementing higher-order Suzuki-Trotter decompositions (Schollwöck, 2011).

Like DMRG, the infinite time-evolving block decimation (iTEBD) method (Kjäll et al., 2013; Vidal, 2007) is based on a MPS representation of the wave function and is suitable for the simulation of one-dimensional lattice problems. iTEBD assumes a state with translational symmetry (the same $\mathcal{A}$ matrix for each site) and treats the system in the thermodynamic limit. The initial ground state of the system is prepared by an imaginary time evolution, i.e., by the application of the operator $\lim_{\beta \rightarrow \infty} e^{-\beta H}$, so that iTEBD should be regarded as a power method, in contrast to DMRG, which employs a variational ground state search.

Within iTEBD, response functions $-i\langle [C(t), D(0)] \rangle$ with bosonic operators C and D , such as the optical conductivity, can be computed by applying a small perturbation proportional to D at time zero. The single particle Green's function can be evaluated by introducing an auxiliary band and measuring the excitations from the system to this auxiliary band (Murakami et al., 2021; Zawadzki and Feiguin, 2019).

Density-functional based methods

Time-dependent density functional theory

Density functional theory (DFT) in combination with the local density approximation (LDA) or generalized gradient approximation (GGA) is based on a nearly homogeneous electron gas treatment of correlations (Kohn and Sham, 1965). This approach is highly successful for weakly correlated materials, but fails to describe strongly correlated systems. Time-dependent DFT (TDDFT) computes the nonequilibrium dynamics of the electron density $n(r, t)$ by solving the time-dependent Kohn-Sham equations (Runge and Gross, 1984)

$$i\partial_t |\psi_j(t)\rangle = H[n](t) |\psi_j(t)\rangle, \quad (6)$$

$$n(r, t) = \sum_j \rho_j \left| \langle r | \psi_j(t) \rangle \right|^2, \quad (7)$$

where $|\psi_j\rangle$ denotes the Kohn-Sham orbitals and ρ_j the corresponding occupations. The Hamiltonian in Eq. (6) contains the kinetic term T , the external potential $V_{\text{ext}}(t)$ describing the effects of the nuclei and possible external fields, the Hartree potential $V_H[n(r, t)]$ and the exchange correlation potential $V_{\text{xc}}[n(r, t)]$. Depending on the gauge choice, an electric field perturbation may enter in the kinetic term or in the external potential. In a gauge with pure vector potential A , where a uniform electric field E is related to A by $E(t) = -\partial_t A(t)$, the kinetic term becomes $T = \frac{1}{2}(-i\nabla - A(t))^2$. In finite-size systems, it can instead be convenient to add a scalar potential $E(t) \cdot r$ to $V_{\text{ext}}(t)$.

Functionals derived from DFT+U

By adding a local Hubbard U to the most strongly correlated orbitals (DFT+ U method (Liechtenstein et al., 1995)) a better description of the electronic structure of correlated systems can be obtained, although DFT+ U , lacking the imaginary part of the self-energy, cannot properly describe Mott physics. Comparing the Hartree-Fock expression for the on-site energy to the energy correction in terms of an effective Hubbard U and Hund coupling J used in DFT+ U , Agapito et al., 2015 derived a functional of the electron density, called ACBN0 functional, which incorporates ab-initio derived U and J parameters. The functional representing the “+ U ” operator has the form

$$V_U^{\sigma}[n, \{\rho_{mm'}^{\sigma}\}] = (U - J) \sum_{m, m'} \left(\frac{1}{2} \delta_{mm'} - \rho_{mm'}^{\sigma} \right) P_{mm'}^{\sigma}, \quad (8)$$

where $P_{mm'}^\sigma = |\phi_m^\sigma\rangle\langle\phi_{m'}^\sigma|$ is the projector to the subspace defined by the localized orbitals $\{\phi_m^\sigma\}$ and ρ^σ is the density matrix of this subspace. The explicit formulas defining U and J in terms of the occupations can be found in (Agapito et al., 2015).

With the above potential, the time-dependent Kohn Sham equation (6) reads (Tancogne-Dejean et al., 2017)

$$i\partial_t |\psi_{v,k}^\sigma\rangle = \left(-\frac{1}{2}\nabla^2 + V_{\text{ext}}(t) + V_H[n(r,t)] + V_{\text{xc}}[n(r,t)] + V_U^\sigma[n(r,t), \{\rho_{mm'}^\sigma\}] \right) |\psi_{v,k}^\sigma(t)\rangle, \quad (9)$$

where $|\psi_{v,k}^\sigma\rangle$ represents a Bloch state with band index v , momentum k , and spin index σ and we assume that a possible electric field excitation enters through $V_{\text{ext}}(t)$.

Functionals derived from DMFT

An alternative and potentially more accurate strategy for incorporating strong correlation effects into (TD)DFT calculations is to compute an exchange-correlation functional from density-dependent energy estimates based on dynamical mean field theory (DMFT), see Section “Nonequilibrium dynamical mean field theory.” For the Hubbard model, this approach was explored by Karlsson et al., 2011. In a spin-independent formulation, the total energy of the Hubbard model can be expressed as $E[n] = E_{\text{kin}}[n] + E_H[n] + E_{\text{xc}}[n] + \sum_i V_{\text{ext},i} n_i$, where $V_{\text{ext},i}$ denotes the external potential at site i , $n_i = \sum_\sigma n_{i\sigma}$, $E_H[n] = \frac{1}{4} \sum_i U_i n_i^2$ the Hartree energy for a possibly site dependent interaction U_i , and $E_{\text{kin}}[n]$ the kinetic energy. The exchange-correlation potential V_{xc} can be calculated within the local density approximation as $V_{\text{xc},i} = V_{\text{xc}}(n_i)$, with V_{xc} derived from the exchange-correlation energy E_{xc} of the homogeneous Hubbard model. If this homogeneous reference system is treated within DMFT, one obtains $E_{\text{xc}} = E_{\text{DMFT}} - E_{\text{kin}} - E_H$, with E_{DMFT} the DMFT estimate of the ground state energy. Computing the derivative of $E_{\text{xc}}[n]$ with respect to n numerically, one obtains the exchange-correlation potential. This potential exhibits a discontinuity at $n = 1$ in the strongly correlated regime (Karlsson et al., 2011), which is a manifestation of the Mott transition in this DFT description.

Green's function based methods

Lattice simulations

Nonequilibrium Green's function method

The nonequilibrium Green's function (NEGF) method is a general and versatile approach for studying the nonequilibrium properties of lattice systems (Stefanuucci and van Leeuwen, 2013). This approach is based on the numerical solution of the Kadanoff-Baym equations (KBes) for the single-particle Green's function

$$G_k(t, t') = -i \langle \mathcal{T}_C c_k(t) c_k^\dagger(t') \rangle, \quad (10)$$

which is expressed here in momentum space. The time arguments lie on an L-shaped contour $\mathcal{C}$ in the complex plane, which runs from time 0 to some maximum time t_{max} along the real-time axis, back to time zero along the real-time axis, and finally to $-i\beta$ along the imaginary time axis, where β is the inverse temperature of the initial equilibrium state (Aoki et al., 2014). $\mathcal{T}_C$ is the contour ordering operator, which orders creation and annihilation operators along $\mathcal{C}$, and the expectation value is defined as $\langle \mathcal{T}_C \dots \rangle = \text{Tr}[\mathcal{T}_C e^{-i \int_{\mathcal{C}} d\bar{t} H(\bar{t})} \dots] / Z$ with H the Hamiltonian and $Z = \text{Tr}[\mathcal{T}_C e^{-i \int_{\mathcal{C}} d\bar{t} H(\bar{t})}]$ the partition function. Denoting the quadratic part of the lattice Hamiltonian by h_k and the self-energy by Σ_k , the single-particle Green's function satisfies

$$(i\partial_t - h_k(t))G_k(t, t') - \int_{\mathcal{C}} d\bar{t} \Sigma_k(t, \bar{t}) G_k(\bar{t}, t') = \delta_{\mathcal{C}}(t, t'), \quad (11)$$

where $\delta_{\mathcal{C}}$ denotes the delta-function on the L-shaped contour. For the numerical solution, Eq. (11) is converted into coupled integro-differential equations for the different components, e.g., the Matsubara (M), greater (>), lesser (<) and left-mixing (l) components of the two-time correlators (Aoki et al., 2014). The resulting KBes for the real-time propagation are

$$i\partial_t G_k^>(t, t') = h_k(t) G_k^>(t, t') + [\Sigma_k * G_k]^>(t, t'), \quad (12)$$

$$-i\partial_t G_k^<(t, t') = G_k^<(t, t') h_k(t) + [G_k * \Sigma_k]^<(t, t'), \quad (13)$$

$$i\partial_t G_k^l(t, \tau) = h_k(t) G_k^l(t, \tau) + [\Sigma_k * G_k]^l(t, \tau). \quad (14)$$

The convolutions are defined by the Langreth rules (Stefanuucci and Leeuwen, 2013)

$$[A_k * B_k]^>(t, t') = \int_0^t d\bar{t} A_k^R(t, \bar{t}) B_k^>(\bar{t}, t') + \int_0^{t'} d\bar{t} A_k^>(t, \bar{t}) B_k^A(\bar{t}, t') - i \int_0^\beta d\tau A_k^l(t, \tau) B_k^l(\tau, t')$$

and

$$[A_k * B_k]^l(t, \tau) = \int_0^t d\bar{t} A_k^R(t, \bar{t}) B_k^l(\bar{t}, \tau) + \int_0^\beta d\tau' A_k^l(t, \tau') B_k^M(\tau' - \tau),$$

which also involve the retarded (R), advanced (A) and right-mixing ($\bar{}$) components. Given the self-energy Σ_k , one first computes the Matsubara component $G_k^M(\tau)$, which captures the initial correlations, and provides the initial conditions for the solution of Eqs. (12)–(14).

Observables

The nonequilibrium Green's functions $G_{k\sigma}(t, t')$ and corresponding spin-densities $n_{k\sigma}(t) = -iG_{k\sigma}^<(t, t)$ allow to compute the relevant observables. The kinetic energy per lattice site is

$$E_{\text{kin}}(t) = \frac{1}{N_k} \sum_{k\sigma} \varepsilon_k(t) n_{k\sigma}(t), \quad (15)$$

with ε_k the noninteracting dispersion and N_k the number of k points in the discretized Brillouin zone. The potential energy per lattice site of the Hubbard model can be evaluated as (Eckstein et al., 2010)

$$E_{\text{pot}}(t) = -\frac{i}{2N_k} \sum_k \text{Tr}[\Sigma_k * G_k]^<(t, t), \quad (16)$$

where the star symbol represents a convolution on the contour $\mathcal{C}$ and the trace is over the spin degree of freedom. The Fourier transforms of the retarded and lesser Green's functions yield the time-dependent spectral function A_k and occupation function $A_k^<$,

$$A_k(\omega, t) = -\frac{1}{\pi} \text{Im} \int_t^\infty dt' e^{i\omega(t'-t)} G_k^R(t, t'), \quad (17)$$

$$A_k^<(\omega, t) = \frac{1}{2\pi} \text{Im} \int_t^\infty dt' e^{i\omega(t'-t)} G_k^<(t, t'). \quad (18)$$

While in a nonequilibrium situation, $A_k(\omega, t)$ and $A_k^<(\omega, t)$ are not guaranteed to be positive, this is the case for the time-resolved photo-emission spectrum (Freericks et al., 2009). This spectrum can be evaluated from the Fourier integral $I_k(\omega, t_p)$, which involves convolutions with the envelope function $S(t)$ of the probe pulse, centered at probe time t_p ,

$$I_k(\omega, t_p) = -i \int dt dt' S(t) S(t') e^{i\omega(t'-t)} G_k^<(t + t_p, t' + t_p). \quad (19)$$

For physically meaningful (gauge invariant) results, one should use gauge invariant Green's functions (Aoki et al., 2014).

A time-dependent electric field can be incorporated into a single-band model like Eq. (1) via the Peierls substitution (Peierls, 1933), which in a gauge with pure vector potential adds a complex phase to the hopping terms: $t_{\text{hop},ij}(t) = t_{\text{hop},ij} \exp[-i \int_{R_i}^{R_j} d\mathbf{r} \cdot \mathbf{A}(\mathbf{r}, t)]$. For optical frequencies, the electric field varies little on the atomic scale, so that the vector potential $\mathbf{A}(\mathbf{r}, t)$ can be approximated as r -independent. In this case, the Peierls substitution corresponds to a time-dependent dispersion $\varepsilon_k(t) = \varepsilon_{k-A(t)}$. The current density can be evaluated as (Aoki et al., 2014)

$$\mathbf{j}(t) = \frac{1}{L^D} \sum_{k\sigma} \mathbf{v}_k(t) n_{k\sigma}(t), \quad (20)$$

with $\mathbf{v}_k(t) = \frac{\partial \varepsilon_k(t)}{\partial \mathbf{k}} = \mathbf{v}_{k-A(t)}$ the shifted band velocity and L^D the volume. A possible strategy for computing the time- and frequency dependent optical conductivity is to apply a half-cycle electric field pulse $E_{t_p}(t)$ centered at probe time t_p , using $E(t) = -\partial_t A(t)$. From the Fourier transformations of $E_{t_p}(t)$ and the induced current $\mathbf{j}_{t_p}(t)$, one obtains $\sigma(\omega, t_p) = \mathbf{j}_{t_p}(\omega)/E_{t_p}(\omega)$.

Self-energy approximations

Given the exact self-energy and initial state, Eqs. (12)–(14) yield the exact nonequilibrium dynamics. In practice, however, NEGF based lattice simulations often involve approximations of the self-energy, which restrict the validity of the simulations to the weak-to-moderate correlation regime. The simplest treatment is the Hartree or Hartree-Fock approximation, which only considers the corresponding time-local self-energy diagrams (first two diagrams in Fig. 1). At the next level one may consider self-energy contributions up to the second order in the interaction. This yields the second-Born (2B) approximation, whose diagrammatic representation for a model with local and nonlocal interactions is shown in Fig. 1. Using the Feynmann rules, these diagrams can be expressed on the L-shaped contour $\mathcal{C}$, and the resulting self-energy components inserted into Eqs. (12)–(14).

Fig. 1 Feynmann diagrams representing the second-Born approximation for the U - V Hubbard model. The first two diagrams represent the Hartree and Fock contributions, the third diagram the direct term, and the fourth diagram the exchange term. The Fock and exchange diagrams are nonzero in the presence of a nonlocal interaction V .

Other commonly used schemes are the GW approximation, which corresponds to the lowest-order self-energy correction in an expansion in terms of the dynamically screened interaction W , and the T-matrix approximation, which sums up ladder-type diagrams (Stefanucci and van Leeuwen, 2013).

Hartree approximation

A simple, but relevant problem is the Hartree dynamics in the antiferromagnetic phase of the Hubbard model (Tsuji et al., 2013), which is equivalent to the time-dependent BCS dynamics (Barankov and Levitov, 2006; Yuzbashyan and Dzero, 2006). The computational scheme can be formulated in terms of the momentum distribution functions

$$\rho_{k\sigma}^{ab}(t) = -iG_{k\sigma}^{ab<}(t, t) \quad (21)$$

with $a, b = A, B$ denoting sublattice indices. The nonequilibrium Green's function satisfies the 2×2 Dyson equation

$$\begin{pmatrix} i\partial_t + \mu - \Sigma_\sigma^A & -\varepsilon_k \\ -\varepsilon_k & i\partial_t + \mu - \Sigma_\sigma^B \end{pmatrix} * \begin{pmatrix} G_{k\sigma}^{AA} & G_{k\sigma}^{AB} \\ G_{k\sigma}^{BA} & G_{k\sigma}^{BB} \end{pmatrix} = \begin{pmatrix} \delta_C & 0 \\ 0 & \delta_C \end{pmatrix}, \quad (22)$$

and the corresponding conjugate equation (Tsuji et al., 2013), where Σ_σ^a is the Hartree self-energy for sublattice a and $*$ denotes a convolution on the time arguments. The explicit expressions for the Hartree self-energies are

$$\Sigma_\sigma^A(t, t') = U(t)n_\sigma^A(t)\delta_C(t, t'), \quad (23)$$

$$\Sigma_\sigma^B(t, t') = U(t)n_\sigma^B(t)\delta_C(t, t'), \quad (24)$$

with $n_\sigma^a(t)$ the local density on sublattice a . In a system with antiferromagnetic order, the local densities can be expressed as

$$n_\sigma^A(t) = \bar{n} + \frac{1}{2}\sigma m(t), \quad n_\sigma^B(t) = \bar{n} - \frac{1}{2}\sigma m(t), \quad (25)$$

where $\bar{n}$ is the average spin-density per site and $m(t)$ is the staggered magnetization. Using the Dyson equation (22) and its conjugate together with Eqs. (23) and (24), one obtains a closed set of equations for the equal-time lesser Green's functions. One may then replace these equal-time functions by the corresponding momentum distribution functions (Eq. (21)), to obtain the following set of equations,

$$\partial_t [\rho_{k\sigma}^{AA}(t) + \rho_{k\sigma}^{BB}(t)] = 0, \quad (26)$$

$$\partial_t [\rho_{k\sigma}^{BA}(t) + \rho_{k\sigma}^{AB}(t)] = -iU(t)m(t)\sigma [\rho_{k\sigma}^{BA}(t) - \rho_{k\sigma}^{AB}(t)], \quad (27)$$

$$i\partial_t [\rho_{k\sigma}^{BA}(t) - \rho_{k\sigma}^{AB}(t)] = 2\varepsilon_k [\rho_{k\sigma}^{AA}(t) - \rho_{k\sigma}^{BB}(t)] + U(t)m(t)\sigma [\rho_{k\sigma}^{BA}(t) + \rho_{k\sigma}^{AB}(t)], \quad (28)$$

$$\partial_t [\rho_{k\sigma}^{AA}(t) - \rho_{k\sigma}^{BB}(t)] = -2i\varepsilon_k [\rho_{k\sigma}^{BA}(t) - \rho_{k\sigma}^{AB}(t)]. \quad (29)$$

These equations can be rewritten in a more transparent form by adopting a pseudospin representation (Anderson, 1958)

$$f_k^x(t) = \frac{1}{2} \sum_\sigma [\rho_{k\sigma}^{BA}(t) + \rho_{k\sigma}^{AB}(t)], \quad (30)$$

$$f_k^y(t) = \frac{1}{2} \sum_\sigma \sigma [\rho_{k\sigma}^{BA}(t) - \rho_{k\sigma}^{AB}(t)], \quad (31)$$

$$f_k^z(t) = \frac{1}{2} \sum_\sigma \sigma [\rho_{k\sigma}^{AA}(t) - \rho_{k\sigma}^{BB}(t)]. \quad (32)$$

With the pseudospins $f_k = (f_k^x, f_k^y, f_k^z)$, the Hartree equations can be expressed as “Bloch equations,”

$$\partial_t f_k(t) = b_k(t) \times f_k(t), \quad (33)$$

where the effective magnetic field is defined as $b_k(t) = (-2\varepsilon_k, 0, U(t)m(t))$. The order parameter is selfconsistently determined by

$$m(t) = \sum_k f_k^z(t). \quad (34)$$

Equation (33) is equivalent to the time-dependent BCS equation (Barankov and Levitov, 2006; Yuzbashyan and Dzero, 2006). It is integrable and has infinitely many conserved quantities. For example, $\rho_{k\sigma}^{AA} + \rho_{k\sigma}^{BB}$ (Eq. 26) and the length of the pseudospin $|f_k| \equiv \sqrt{(f_k^x)^2 + (f_k^y)^2 + (f_k^z)^2}$ are conserved for each k .

As an illustration, the left panel of Fig. 2 shows the Hartree solution for the time evolution of the staggered magnetization $m(t)$ in a Hubbard model on a Bethe lattice with a semi-circular density of states of bandwidth 4. The interaction $U(t)$ is ramped linearly from the initial value $U_i = U(t=0) = 2$ to the indicated final values $U_f = U(t \geq t_f)$ in a time $t_f = 8$. This ramp to lower interactions

Fig. 2 Time evolution of the staggered magnetization m after an interaction ramp in the Hubbard model on a Bethe lattice with bandwidth 4. The left panel shows the result of the Hartree approximation and the right panel the DMFT result obtained with the third order weak-coupling expansion as impurity solver. Here, the arrows indicate the thermalized value of m , calculated from the total energy after the ramp.

results in two qualitatively different time evolutions. For $U_f \geq 1.2$ the solution oscillates around a nonzero m , which implies that within the Hartree approximation, the magnetic order survives, while for $U_f = 1.0$, the order parameter decays monotonically to zero (Tsuji et al., 2013). Analogous results are obtained for the BCS dynamics in the case of an attractive U (Barankov and Levitov, 2006; Yuzbashyan and Dzero, 2006).

Generalized Kadanoff-Baym ansatz

Equation of motion

A more sophisticated formalism, which also reduces the KBEs (12)–(14) to an equation of motion for the density matrix, is the generalized Kadanoff-Baym ansatz (GKBA) (Lipavsky et al., 1986). For the following discussion, we define $\rho_k^<(t) = -iG_k^<(t, t)$. The equation of motion for $\rho_k^<(t)$ is

$$\frac{d}{dt}\rho_k^<(t) = -i[h^{\text{MF}}(t), \rho_k^<(t)] - [\mathcal{I}_k(t) + \text{h.c.}], \quad (35)$$

with h^{MF} denoting the mean-field Hamiltonian, while the collision term $\mathcal{I}_k(t)$ is defined by

$$\mathcal{I}_k(t) = [\Sigma_k * G_k]^<(t, t). \quad (36)$$

The time off-diagonal components of the lesser and greater Green's function, which are needed for the collision integral (36), are reconstructed by the GKBA from the diagonal $\rho_k^<(t)$ as

$$G_k^>(t, t') = -G_k^{\text{R}}(t, t')\rho_k^<(t') + \rho_k^<(t)G_k^{\text{A}}(t, t'). \quad (37)$$

Typically, the Hartree-Fock (HF) Hamiltonian h^{HF} , which is a functional of $\rho_k^<$, is used to compute an approximate retarded Green's function,

$$G_k^{\text{R}}(t, t') = -i\theta(t-t')\mathcal{T} \exp\left(-i\int_{t'}^t d\bar{t} h_k^{\text{HF}}(\bar{t})\right) \equiv -i\theta(t-t')U_k(t, t'), \quad (38)$$

while $G_k^{\text{A}}(t, t') = [G_k^{\text{R}}(t', t)]^\dagger$. Here, $\mathcal{T}$ is the usual time ordering symbol. The time-evolution operator $U_k(t, t')$ defined by Eq. (38) can be evaluated on a uniform mesh of time points $t_n = n\delta t$ using $U_k(t_n + \delta t, t_j) = U_k(t_n + \delta t, t_n)U_k(t_n, t_j)$, where $U_k(t_n + \delta t, t_n)$ is computed, for example, with the commutator-free matrix-exponential method (Alvermann and Fehske, 2011).

In the full NEGF calculation, the initial equilibrium state is calculated on the imaginary branch of the L shaped contour. For the GKBA, however, the corresponding equilibrium approximation is not known. Thus, the many-body effects are switched on adiabatically, in a time propagation within the GKBA which starts from a noninteracting or a mean-field initial state. In this calculation, the self-energy corrections are slowly built in using a ramp function, while the system evolves to the correlated equilibrium state.

Linear-scaling algorithm

Because of the convolution in the collision term (36) the solution of the equation of motion (35) scales at least quadratically in the maximum number N_t of time steps. This scaling can for example be achieved with the second Born approximation.

Schlünzen et al., 2020 showed that it is possible to reduce the computational effort to $\mathcal{O}(N_t)$ by rewriting the problem in the form of coupled equations for the time-diagonal parts of the single-particle and two-particle Green's functions. In the following, the

equations are presented for the Hubbard model, using real space Green's functions. A more general and detailed discussion can be found in (Joost et al., 2020).

Expressed in real space, the equation of motion for the time-diagonal part of the single-particle Green's function $G_{ij} = -i\langle T c_i(t) c_j^\dagger(t') \rangle$ or density matrix $\rho_{ij\sigma}^<(t) = -iG_{ij\sigma}^<(t, t)$ takes the form

$$\frac{d}{dt} \rho_{ij\sigma}^<(t) = -i[h^{\text{HF}}(t), \rho^<(t)]_{ij\sigma} - [\mathcal{I}_{ij\sigma}(t) + \text{h.c.}], \quad (39)$$

where the Hartree-Fock Hamiltonian reads $h_{ij\sigma}^{\text{HF}}(t) = h_{ij}^{(0)} + \delta_{ij}U(t)\rho_{ii\sigma}^<(t)$ and the collision term $\mathcal{I}_{ij\sigma}(t) = -iU(t)\mathcal{G}_{ij\sigma}^{\sigma\bar{\sigma}\sigma\bar{\sigma}}(t)$ is related to the two-particle Green's function

$$G_{ijkl}^{(2)}(t_1, t_2, t_3, t_4) = (-i)^2 \langle T c_i(t_1) c_j(t_2) c_l^\dagger(t_4) c_k^\dagger(t_3) \rangle, \quad (40)$$

which can be decomposed into a Hartree, a Fock and a correlation contribution: $G_{ijkl}^{(2)} = G_{ijkl}^{(2),\text{H}} - G_{ijkl}^{(2),\text{F}} + G_{ijkl}^{(2),\text{corr}}$. The time-diagonal two-particle Green's function $\mathcal{G}_{ijkl}(t)$ appearing in the collision term is defined as

$$\mathcal{G}_{ijkl}(t) = [\mathcal{G}_{ijkl}^{(2),\text{corr}}]^<(t, t). \quad (41)$$

The equation of motion for this time-diagonal function reads

$$-i \frac{d}{dt} \mathcal{G}_{ijkl}^{\sigma\bar{\sigma}\sigma\bar{\sigma}}(t) = -[h_{\sigma\bar{\sigma}}^{(2),\text{HF}}, \mathcal{G}_{ijkl}^{\sigma\bar{\sigma}\sigma\bar{\sigma}}]_{ijkl}(t) + U(t)\Phi_{ijkl}^{\sigma\bar{\sigma}\sigma\bar{\sigma}}(t), \quad (42)$$

where $h_{ijkl,\sigma\bar{\sigma}}^{(2),\text{HF}}(t) = \delta_{jl}h_{ik}^{\text{HF},\sigma}(t) + \delta_{ik}h_{jl}^{\text{HF},\bar{\sigma}}(t)$ and

$$\Phi_{ijkl}^{\sigma\bar{\sigma}\sigma\bar{\sigma}}(t) = \sum_p [\rho_{ip\sigma}^>(t)\rho_{jp\bar{\sigma}}^>(t)\rho_{pk\sigma}^<(t)\rho_{pl\bar{\sigma}}^<(t) - \rho_{ip\sigma}^<(t)\rho_{jp\bar{\sigma}}^<(t)\rho_{pk\sigma}^>(t)\rho_{pl\bar{\sigma}}^>(t)]. \quad (43)$$

Since $\Phi_{ijkl}^{\sigma\bar{\sigma}\sigma\bar{\sigma}}(t)$, and hence the right-hand side of Eq. (42), involves no memory term, the solution of the coupled equations (39) and (42) is linear in N_t .

Nonequilibrium dynamical mean field theory

Formalism

Nonequilibrium dynamical mean field theory (Aoki et al., 2014; Freericks et al., 2006) is a Green's function based formalism which becomes exact in the limit of infinite dimension or infinite coordination number. If applied to finite-coordination systems, DMFT becomes an approximate description, which however works directly in the thermodynamic limit. DMFT neglects the nonlocal self-energy components, but captures strong local correlation effects.

DMFT maps a correlated lattice model onto a self-consistently determined effective quantum impurity model (Georges et al., 1996). As illustrated in Fig. 3, this mapping is performed by identifying the self-energy of the lattice model, Σ_k^{latt} , with the local impurity self-energy Σ_{imp} (DMFT approximation), while the bath properties of the impurity model are fixed by a self-consistency condition which demands that the local lattice Green's function is identical to the impurity Green's function, $G_{\text{loc}}^{\text{latt}} = \frac{1}{N_k} \sum_k G_k^{\text{latt}} \equiv G_{\text{imp}}$ (DMFT self-consistency condition). Often it is convenient to work in an action formalism, where the bath of the impurity model is represented by a hybridization function Δ . This function encodes how electrons hop in and out of the impurity site and thus plays the role of a dynamical mean field.

The self-consistent mapping from a lattice model to an impurity model can be implemented also for nonequilibrium systems (Freericks et al., 2006). The only difference in nonequilibrium DMFT, compared to equilibrium DMFT, is that the functions $G(t, t')$, $\Sigma(t, t')$ and $\Delta(t, t')$ are functions defined on the L-shaped contour $\mathcal{C}$ in the complex time-plane instead of the imaginary-time axis (Aoki et al., 2014). Since a general nonequilibrium state has no time-translation invariance, these functions depend on the two times t and t' separately, rather than on the time difference as in equilibrium. This implies a higher memory cost for storing these functions, and it also means that Dyson's equation cannot be simply solved by Fourier transformation. Instead, it has to be solved on the real-time branches of the contour $\mathcal{C}$ as an integro-differential equation, in which the self-energy plays the role of a memory kernel (Eckstein et al., 2010), see Eq. (11). If the full memory is retained, the solution of Dyson's equation scales like the third power in the maximum number N_t of time steps on the real-time branches. In many situations, however, this scaling can be reduced to linear in N_t by the use of memory truncations (Stahl et al., 2022).

In the case of the Hubbard model the effective impurity problem is an Anderson impurity model with action

$$S_{\text{imp}} = \int_{\mathcal{C}} dt dt' \sum_{\sigma} c_{\sigma}^{\dagger}(t) \Delta_{\sigma}(t, t') c_{\sigma}(t') - \mu \int_{\mathcal{C}} dt \sum_{\sigma} n_{\sigma}(t) + \int_{\mathcal{C}} dt U(t) n_{\uparrow}(t) n_{\downarrow}(t). \quad (44)$$

The local self-energy yields, via the Dyson equation, the momentum-dependent lattice Green's functions $G_k(t, t')$ which may then be used to compute the observables (15)–(20). The impurity model also gives access to the time-dependent double occupation

$$d(t) = \langle n_{\uparrow}(t) n_{\downarrow}(t) \rangle, \quad (45)$$

Fig. 3 Top panel: Self-consistent mapping of a lattice model to an effective impurity model in DMFT. Bottom panel: Selfconsistency loop, where S_{imp} is the impurity action with hybridization function Δ , G_{imp} is the impurity Green's function and Σ_{imp} the self-energy of the impurity model. By approximating the self-energy of the lattice Σ_k^{latt} by the impurity selfenergy, one obtains an approximation for the lattice Green's function G_k^{latt} .

and hence the potential energy per site $E_{\text{pot}}(t) = U d(t)$ of the Hubbard model. The kinetic energy can be evaluated directly from the impurity model (Aoki et al., 2014), via a convolution of the impurity Green's function and the hybridization function,

$$E_{\text{kin}}(t) = -i \text{Tr} [G_{\text{imp}}^* \Delta]^{<}(t), \quad (46)$$

where the trace is the sum over the two spin contributions.

Impurity solvers

A numerically challenging task in nonequilibrium DMFT simulations is the solution of the impurity problem, i.e., the calculation of the impurity Green's function or impurity self-energy from the action (44). This subsection presents nonequilibrium impurity solvers which have proven useful in the DMFT context.

Weak-coupling solvers. In weakly correlated systems, perturbative approaches such as the iterated perturbation theory (IPT) (Georges et al., 1996), which corresponds to a second order expansion of the impurity selfenergy, may be adequate. The IPT self-energy of the Hubbard model is given by the first and third diagram in Fig. 1, but evaluated here with bath Green's functions $\mathcal{G}_\sigma(t, t') = [\delta_C(t, t') (i\partial_t + \mu) - \Delta_\sigma(t, t')]^{-1}$ (bare IPT) or with correlated impurity Green's functions $G_{\text{imp},\sigma}(t, t')$ (boldified IPT). The boldified version is conserving, but the short-time dynamics is more accurately described by the bare IPT (Eckstein et al., 2010).

The explicit form of the second-order bare IPT selfenergy is

$$\Sigma_\sigma^{(2)}(t, t') = U(t)U(t')\mathcal{G}_\sigma(t, t')\mathcal{G}_{\bar{\sigma}}(t', t)\mathcal{G}_{\bar{\sigma}}(t, t'). \quad (47)$$

Weak coupling solvers up to fourth order in U , and with different treatments of the Hartree term, have been discussed and benchmarked in Tsuji and Werner, 2013. As an example of an application of the third-order solver, the right panel of Fig. 2 shows the time evolution of the staggered magnetization m in the moderately correlated Hubbard model after interaction ramps. The setup is the same as for the Hartree calculation illustrated in the left panel. One finds that at early times, the dynamics in DMFT + 3rd order is qualitatively similar to the Hartree solution, in the sense that below a critical final interaction, the order parameter decays monotonically to zero, whereas for interactions above this critical value, there are oscillations around a nonzero value of m . However, in contrast to the Hartree solution, the DMFT result exhibits strongly damped oscillations, and for final interactions $U_f \leq 1.4$ the solution relaxes at long times to a paramagnetic state. Also for larger interactions, like $U_f = 1.4$, the solution eventually approaches a thermalized value with a reduced m , as indicated by the arrow. Hence, DMFT does not only capture the transient trapping in a prethermalized state with a nonthermal value of the order parameter, but also the thermalization dynamics.

QMC solvers. Independent of the interaction strength, an exact solution can in principle be obtained by the weak-coupling continuous-time Monte Carlo method (Rubtsov et al., 2005; Werner et al., 2010). Here, one first re-expresses the local terms of the Anderson impurity model using a spin-dependent chemical potential shift,

$$H_{\text{loc}}(t) = U(t)(n_\uparrow - \alpha_\uparrow)(n_\downarrow - \alpha_\downarrow) - \sum_\sigma [\mu - U(t)\alpha_\sigma]n_\sigma. \quad (48)$$

With a suitable choice of α_σ , this avoids a trivial sign problem in the repulsively interacting case (Rubtsov et al., 2005). The first term proportional to $U(t)$ corresponds to the modified interaction H_{int} . Expanding the partition function $Z = \text{Tr} [\mathcal{T}_C e^{-iS_{\text{imp}}}]$ in powers of H_{int} and separating the trace into spin-up and spin-down factors leads to

$$\frac{Z}{Z_0} = \sum_n \frac{(-i)^n}{n!} \int_C dt_1 \dots \int_C dt_n U(t_1) \dots U(t_n) \times \prod_\sigma \langle (n_\sigma(t_1) - \alpha_\sigma) \dots (n_\sigma(t_n) - \alpha_\sigma) \rangle_{S_0}, \quad (49)$$

with $Z_0 = \text{Tr}[\mathcal{T}_C e^{-iS_0}]$ and S_0 the noninteracting part of the shifted impurity action. Wick's theorem allows to express the expectation values in Eq. (49) as the determinant of an $n \times n$ matrix M_σ^{-1} , with elements

$$(M_\sigma^{-1})_{ij} = -i\mathcal{G}_{0,\sigma}(t_i, t_j) - \alpha_\sigma \delta_{ij}, \quad (50)$$

$$\mathcal{G}_{0,\sigma}(t, t') = -i\langle \mathcal{T}_C c_\sigma(t) c_\sigma^\dagger(t') \rangle_{S_0}, \quad (51)$$

and the convention $\mathcal{G}_{0,\sigma}(t, t) \equiv \mathcal{G}_{0,\sigma}^<(t, t)$. Eq. (49) therefore expresses $Z/Z_0 = \sum_c w(c)$ as a sum over configurations $c = \{t_1 < t_2 < \dots < t_n\}$ consisting of collections of (cyclically ordered) time-points on the contour $\mathcal{C}$. The weight of the configuration c is

$$w(c) = (-i)^n (U(t_1)dt_1) \dots (U(t_n)dt_n) \prod_\sigma \det M_\sigma^{-1}. \quad (52)$$

Here, $dt_i = dt$ for t_i on the forward branch, $-dt$ for t_i on the backward branch, and $-id\tau$ for t_i on the imaginary time branch.

A Monte Carlo sampling over all configurations c can be implemented on the basis of these weights (Werner et al., 2009). The determinants in Eq. (52) sum up all the $n!$ connected and disconnected bare diagrams for a given set of n interaction vertices. While this summation (for a proper choice of the α_σ) absorbs the sign cancellations originating from Fermi statistics, the weights $w(c)$ are in general complex. The Monte Carlo sampling thus suffers from a dynamical sign problem. This problem grows exponentially with the length of the real-time contour, and restricts the calculations to relatively short times (Eckstein et al., 2010).

Strong-coupling solvers. A numerically more efficient approximate method for strongly correlated systems sums up a subset of hybridization expansion diagrams. This approach starts from the atomic limit and is thus suitable for the description of Mott insulating states. The lowest order implementation of this scheme is known as the non-crossing approximation (NCA) (Keiter and Kimball, 1971) and the second order implementation as the one-crossing approximation (OCA) (Pruschke and Grewe, 1989). The formulation of these methods and their performance in the nonequilibrium context have been discussed in detail in Eckstein and Werner, 2010. The following discussion presents the main ideas, and the formulas for the NCA.

The partition function of the impurity problem (44), $Z = \text{Tr}[\mathcal{T}_C e^{-iS_{\text{imp}}}]$, can be expressed as an infinite sum over strong-coupling diagrams by performing a power series expansion in $\Delta(t, t')$ (Mühlbacher and Rabani, 2008; Werner et al., 2009). The weight of a given diagram is (up to prefactors) given by the product of hybridization functions and a product of atomic propagators, which represent the time evolution between the hybridization events. The subset of diagrams without crossing hybridization lines can be obtained by introducing pseudoparticles (Aoki et al., 2014). The bare pseudo-particle Green's function $\tilde{g}$ is defined as the matrix of atomic propagators in some basis $\{|n\rangle\}$ of the local Hilbert space. Its elements are $\tilde{g}_{mn}(t, t') = -i\langle m|\mathcal{T}_C e^{-i\int_t^{t'} d\bar{t} H_{\text{loc}}(\bar{t})}|n\rangle$, where the time arguments on $\mathcal{C}$ need to satisfy the contour ordering $t \succ t'$. $\tilde{G}$ denotes the corresponding boldfied pseudo-particle Green's function, which includes the effect of hybridizations. In the lowest order (NCA) approximation, the pseudo-particle self-energy is defined as

$$\tilde{\Sigma}^{\text{NCA}}(t, t') = i \sum_\sigma [\tilde{c}_\sigma^\dagger(t) \tilde{G}(t, t') \tilde{c}_\sigma(t') \Delta_\sigma(t, t') - \tilde{c}_\sigma(t) \tilde{G}(t, t') \tilde{c}_\sigma^\dagger(t') \Delta_\sigma(t', t)], \quad (53)$$

where the tildes on the creation and annihilation operators indicate that these are to be understood as matrices in the chosen basis (e.g., $(\tilde{c}_\sigma)_{mn} = \langle m|c_\sigma|n\rangle$). The sum of all noncrossing diagrams can then be expressed in terms of the elements of $\tilde{G}$, which are the solution of the pseudoparticle Dyson equation $\tilde{G} = \tilde{g} + \tilde{g} * \tilde{\Sigma}^{\text{NCA}} * \tilde{G}$, with a cyclic constraint on the time arguments in the convolutions (for $t \succ t'$, $[A * B](t, t') = \int_{\mathcal{C}, t \succ \bar{t} \succ t'} d\bar{t} A(t, \bar{t}) B(\bar{t}, t')$). The time-propagation of the pseudo-particle Green's functions is always in a clockwise direction around the $\mathcal{C}$ contour, such that for $t < t'$, the lesser component of $\tilde{G}$ is defined as $i\tilde{\xi} \tilde{G}(t, 0_+) \tilde{G}(-i\beta, t')$, with $\tilde{\xi}$ a diagonal matrix with elements $+1(-1)$ for pseudo-particles with an even (odd) number of electrons.

The diagonal elements $i\tilde{G}_{nn}(-i\beta, 0_+)$ represent the contribution of the basis state $|n\rangle$ to the partition function, so that $Z_{\text{NCA}} = i\text{Tr}[\tilde{G}(-i\beta, 0_+)]$. For the measurement of the impurity Green's function, one inserts a creation operator at t' and an annihilation operator at t and evaluates

$$G_\sigma(t, t') = \frac{i}{Z_{\text{NCA}}} \text{Tr}[\tilde{\xi} \tilde{G}(t', t) \tilde{c}_\sigma(t) \tilde{G}(t, t') \tilde{c}_\sigma^\dagger(t')].$$

While NCA produces qualitatively correct results only for strongly correlated systems, where the hybridization can be regarded as a small perturbation, the above procedure can be generalized to higher-order-in- Δ approximations of the self-energy, which systematically converge to the exact result and provide an adequate description in a wide range of parameters (Eckstein and Werner, 2010). A useful property of this approach in nonequilibrium simulations is that it is conserving.

Variants of nonequilibrium DMFT

Floquet DMFT

If a correlated lattice system such as the Hubbard model is driven by a time-periodic electric field or an interaction modulation with frequency Ω , and the injected energy is balanced by dissipation to some heat bath, the system reaches a time-periodic

nonequilibrium steady state. Floquet DMFT (Tsuji et al., 2008) allows to describe this steady state directly, without a simulation of the transient evolution starting from some equilibrium state. The Floquet DMFT formalism is implemented on the two-branch Keldysh contour using a so called Floquet matrix representation of $G(t, t')$, $\Sigma(t, t')$ and $\Delta(t, t')$. To define the Floquet representation, one introduces the average time $t_{\text{av}} = (t + t')/2$ and the relative time $t_{\text{rel}} = (t - t')$ and assumes that all the relevant two-time quantities are periodic with respect to t_{av} , with period $\mathcal{T} = \frac{2\pi}{\Omega}$. For example

$$G(t_{\text{rel}}, t_{\text{av}} + \mathcal{T}) = G(t_{\text{rel}}, t_{\text{av}}), \quad (54)$$

and similarly for the self-energy. The Floquet matrix representation of the Green's function is then defined by

$$G_{nm}(\omega) = \frac{1}{\mathcal{T}} \int_0^{\mathcal{T}} dt_{\text{av}} e^{i(m-n)\Omega t_{\text{av}}} G\left(\omega + \frac{m+n}{2}\Omega, t_{\text{av}}\right), \quad (55)$$

where ω is restricted to the "reduced Brillouin zone" $[-\frac{\Omega}{2}, \frac{\Omega}{2})$. An advantage of this matrix representation is that convolutions of functions satisfying the periodic relation (54) can be expressed as matrix products. The fermionic Dyson equation thus becomes the matrix equation

$$[\underline{G}_0^{-1}(\omega) - \underline{\Sigma}(\omega)]\underline{G}(\omega) = \underline{I}. \quad (56)$$

For the heat bath, one typically considers a bath of noninteracting fermions with finite bandwidth, or a boson bath. The total self-energy of the system is then defined as $\Sigma_{\text{tot}} = \Sigma_{\text{int}} + \Sigma_{\text{bath}}$, where Σ_{int} is the self-energy obtained from the impurity Dyson equation and Σ_{bath} the self-energy originating from the coupling to the heat bath. The Floquet representation of Σ_{tot} enters as $\underline{\Sigma}$ into the lattice Dyson equation and defines the updated lattice Green's function.

Cluster DMFT

To capture the effect of short-range correlations, cluster extensions of DMFT have been developed. This formalism allows to describe the correlations within a small cluster explicitly, while longer-range correlations are treated at the mean-field level. In the dynamical cluster approximation (DCA) approach (Hettler et al., 1998), which has been applied to non-equilibrium problems (Bittner et al., 2020; Eckstein and Werner, 2016; Tsuji et al., 2014), the self-energy Σ_k^{latt} is approximated as constant within certain regions ("patches") of the first Brillouin zone, and identified with the corresponding momentum components of the cluster (impurity) self-energy: $\Sigma_k^{\text{latt}}(t, t') \approx \sum_K \Sigma_K^{\text{imp}}(t, t') \phi_K(k)$, where $\phi_K(k) = 1$ for k inside momentum patch K and zero otherwise. The DCA self-consistency loop for each patch is analogous to Fig. 3, except that the momentum averaging on the lattice side is performed over the corresponding patch, instead of the full Brillouin zone, and that the self-consistency condition identifies this patch-averaged lattice Green's function $G_K^{\text{latt,av}}$ with the cluster impurity Green's function G_K^{imp} for momentum K . The only step in the self-consistency loop where the different momenta are coupled is the solution of the impurity problem, which yields G_K^{imp} and the cluster self-energy Σ_K^{imp} .

For nonequilibrium simulations, the DCA approach is preferred over the cluster DMFT (CDMFT) (Lichtenstein and Katsnelson, 2000) variant, because the diagonal representation in momentum space avoids the memory demanding solution of matrix-valued Dyson equations (Tsuji et al., 2014).

Extended DMFT

The extended DMFT (EDMFT) formalism (Aryal et al., 2013; Si and Smith, 1996; Sun and Kotliar, 2002) allows to treat models with nonlocal interactions, such as the U - V Hubbard model (1) with $V \neq 0$, and the associated dynamical screening effects. Like conventional DMFT, EDMFT maps the lattice system to a single site impurity model, but this model now contains two dynamical mean fields, a fermionic dynamical mean field (hybridization function $\Delta(t, t')$) and a bosonic dynamical mean field, which in the case of the U - V Hubbard model is a self-consistently computed, dynamically screened impurity interaction $\mathcal{U}(t, t')$. These dynamical mean fields are determined by two coupled self-consistency loops, (i) the usual fermionic self-consistency loop which connects the self-energy Σ and (local) Green's function G of the lattice and impurity systems, and fixes Δ , and (ii) a bosonic loop which connects the local polarization Π and local screened interaction W of the lattice and impurity systems, and fixes $\mathcal{U}$. The impurity interaction $\mathcal{U}$ incorporates the effect of nonlocal screening on the local interaction.

A possible nonequilibrium solver for the EDMFT impurity problem is the combined strong/weak-coupling expansion (Golez et al., 2015), where the partition function is expanded in both the hybridization Δ and the retarded part of the interaction, $\mathcal{D}$. In the case of a model with onsite repulsion U the latter is related to the impurity interaction by $\mathcal{U}(t, t') = U\delta_C(t, t') + \mathcal{D}(t, t')$. Within NCA, all the diagrams without crossing Δ and $\mathcal{D}$ lines are summed up, which can be accomplished by defining the pseudoparticle self-energy

$$\tilde{\Sigma}_{\text{strong/weak}}^{\text{NCA}}(t, t') = \tilde{\Sigma}^{\text{NCA}}(t, t') - i\tilde{n}(t)\tilde{G}(t, t')\tilde{n}(t')\mathcal{D}(t', t), \quad (57)$$

with $\tilde{\Sigma}^{\text{NCA}}$ defined in Eq. (53) and $\tilde{n}$ the representation of the density operator in the chosen basis.

W_{imp} and $\mathcal{U}$ are related through the connected impurity charge-charge correlator $\chi_{\text{imp}} = \langle \mathcal{T}_C \bar{n}(t) \bar{n}(t') \rangle$ (with $\bar{n} = n - \langle n \rangle$) through

$$W_{\text{imp}} = \mathcal{U} - \mathcal{U}^* \chi_{\text{imp}}^* \mathcal{U} \quad (58)$$

while the bosonic self-energy Π is obtained by solving the impurity Dyson equation

$$W_{\text{imp}} = \mathcal{U} + \mathcal{U}^* \Pi^* W_{\text{imp}}, \quad (59)$$

where $*$ denotes a convolution on the contour $\mathcal{C}$. The bosonic lattice Dyson equation of the EDMFT scheme reads

$$W_k = V_k + V_k^* \Pi^* W_k, \quad (60)$$

with V_k the Fourier transform of the local and nonlocal interaction. For example, for model (1) with nearest neighbor interactions on the square lattice with lattice spacing a , $V_k = U + 2V(\cos(k_x a) + \cos(k_y a))$.

GW+EDMFT

To incorporate nonlocal correlation and screening effects into the single-site EDMFT formalism for the U - V Hubbard model, a possible strategy is to add nonlocal Σ and Π components taken from the GW approximation (Hedin, 1965) and feed the resulting fermionic and bosonic self-energies back into the self-consistency loop (Aryal et al., 2013; Biermann et al., 2003). In this so-called GW+EDMFT formalism, the lattice self-energy and polarization is approximated as

$$\Sigma_{ij}^{\text{latt}} = \Sigma^{\text{EDMFT}} \delta_{ij} + \Sigma_{ij}^{\text{GW,nonloc}}, \quad (61)$$

$$\Pi_{ij}^{\text{latt}} = \Pi^{\text{EDMFT}} \delta_{ij} + \Pi_{ij}^{\text{GW,nonloc}}, \quad (62)$$

with $\Sigma_{ij}^{\text{GW,nonloc}}(t, t') = iG_{ij}(t, t')W_{ij}(t, t')(1 - \delta_{ij})$ and $\Pi_{ij}^{\text{GW,nonloc}}(t, t') = -iG_{ij}(t, t')C_{ji}(t', t)(1 - \delta_{ij})$ computed from the lattice Green's function and screened interaction. Nonequilibrium applications of this scheme (Golez et al., 2017) have shown that the nonlocal polarization significantly enhances the screening in photo-excited systems, compared to EDMFT.

Abstract

Fundamental issues of 1/f noise in quantum nanoscience are reviewed starting from basic statistical noise processes. Fundamental noise models based on two-level systems (TLSs) are described. We emphasize the importance of TLSs in materials parameter fluctuations, such as dielectric constant. The present understanding of 1/f noise in superconducting quantum interferometers and in single electron devices is summarized. For coherent quantum nanoscience, we introduce superconducting qubits and the relation between decoherence and 1/f noise using the filter function formulation. We also clarify the qubit noise spectroscopy and emphasize the importance of materials with reduced 1/f noise for future quantum coherent nanodevices.

Key points

- Basic characteristics of 1/f noise in condensed matter systems
- Theoretical issues concerning stationarity, ergodicity, and TLS with uniform distribution for tunneling parameter
- Specific features of 1/f noise in nanoscale systems and quantum materials
- Significance of TLS for dissipation in superconducting materials for low-loss quantum circuits
- 1/f noise in quantum circuits and devices, both in the flux and charge fluctuation regimes
- Influence of 1/f noise on coherence properties of qubits
- Role of low-frequency fluctuations in quantum sensing

Introduction

Fluctuations with power spectral density $S(f)$ increasing with decreasing frequency have been observed in a great variety of systems from physics, electronic engineering, and biology to music, economic, and social sciences, even medicine. Solid-state materials and devices have formed the supreme arena where the command of the physics of low-frequency fluctuations has been deeply exploited. Strong motivation comes from both the fundamental research and the quest for electronic devices with improved performance. The advent of modern nanoscience has opened a new era in which this subject has entered the realm of quantum coherence.

Measurements of fluctuations in a vast number of physical systems yield a noise spectral density of the form

$$S(f) = C f^{-\alpha} \quad (1)$$

with α ranging from 0 to 2, down to the lowest measured frequencies $\sim \mu\text{Hz}$. Since values of $\alpha \approx 1$ are typically observed, the phenomenon is called 1/f noise. The alternative terms “flicker noise” or “excess noise” are less frequently used.

In solid-state materials and devices, fluctuations of transport and dielectric properties exhibit a $\sim 1/f$ spectrum in addition to intrinsic thermal noise and quantum (shot) noise (see Fig. 1). They share the same distinctive features such as the frequency dependence of the noise, the time dependence of correlations, weak stationarity, and other statistical properties.

Fig. 1 Qualitative representation of noise spectrum in coherent nanodevices on a log–log scale. Lines describe the expected behavior in different frequency ranges. Dots represent typical observations in frequency windows depending on the noise detection method (different symbols and dots), see discussion in section “1/f noise in quantum-coherent nanodevices.” Long-dashed lines indicate the 1/f dependence between the intrinsic low- and high-frequency cutoffs γ_1 and γ_2 , which in general are not known. Thick lines indicate the 1/f^α dependence, with $\alpha \approx 0.9$. Ω denotes the typical qubit splitting, of the order of 10^{10} Hz in superconducting qubits. In this range, quantum noise is commonly white or Ohmic (dotted and thin lines). The dash-dotted line indicates the linearly increasing Johnson–Nyquist noise.

With the advent of nanofabrication technologies, the number of devices and electronic components showing excess low-frequency noise have increased, and they all share the features of the ubiquitous 1/f noise. Charge fluctuations with 1/f spectrum in substrate materials have been found to influence devices operating in the Coulomb blockade regime where quantized charge in a small, weakly coupled conducting island is acting as the quantum mechanical observable. In the regime of superconducting coherence, flux noise generates unwanted currents with 1/f character, which is detrimental in many magnetic field sensors and superconducting qubits. Also, various heterostructures (including e.g., field effect (FET) and high-electron-mobility transistor (HEMT) structures), either based on materials deposition, modulation doping, or stacking of atomically layered two-dimensional (2D) materials, display 1/f noise in the number of charge carriers owing to charge traps in the vicinity of the active device channel. Beyond electronic and physical systems, 1/f noise is found even in healthy human heartbeat rates.

The appearance of 1/f-like behavior in many phenomena of diverse nature and its scale invariance, that is, the fact that each decade of frequencies contains the same integrated power, suggested that a common, deeper level description may exist, such as for the universality of the exponents in critical phenomena, that is, that 1/f-like behavior is an inherent property of all systems and that a universal minimum frequency exists. However, the large amount of experimental data in solid-state systems indicates that there is no universal spectrum of low-frequency noise.

In modern electronic devices, small active volume bistable switching of the resistance called random telegraph noise (RTN) is observed. The phenomenon is attributed to capture and emission processes from defects suggesting a possible microscopic mechanism of 1/f noise. In fact, in many solid-state systems, experiments are satisfactorily explained by the combined action of many bistable defects or traps. The distribution of the observed physical characteristics accounts for the rather large range of time constants generating 1/f noise.

Besides universality, other fundamental problems have been posed as the necessary existence of low-frequency cutoff to avoid unphysical divergencies and the related questions of stationarity. On the experimental side, it is often difficult to give an unambiguous interpretation of data as the ensemble-averaged power spectra provide incomplete information on individual fluctuators.

While for metals and spin glasses, some understanding of the mechanism of 1/f noise has been developed, the problem is still unsolved for the majority of physical systems. Advances in the study of the microscopic nature are of practical importance since 1/f noise limits the performance of high-end electronic devices and sensors at low frequencies. Devices for metrological applications are also affected since their high operating frequencies show fluctuations with 1/f spectrum.

This chapter focuses on 1/f noise in *quantum nanoscience*. Quantum nanoscience comprises natural or engineered nanoscale systems whose functionality and structure can only be explained through quantum mechanisms such as discretization, superposition, and entanglement (definition from Milburn and Woolley, 2008). These quantum properties facilitate, among other things, the enormous power of quantum information processing as well as novel quantum sensors. However, superposition states are fragile and quickly destroyed by 1/f noise, which needs to be considered for their functional applications. Our scope here is to discuss first the influence of 1/f noise on “traditionally-behaving” nanodevices and sensors, and then describe specific features encountered in the quantum coherent case.

New fundamental problems related to 1/f noise arise in quantum nanoscience and quantum information since the flicker noise may be the main source of decoherence present. For coherent quantum devices such as qubits, this has led to original ways for quantifying the impact of 1/f noise on the qubit, and to strategies for recovering the coherence using well-chosen pulse sequences.

Progress in quantum nanoscience has also provided new tools for the characterization of 1/f noise sources. Nanoelectronic devices can be employed for example to detect charge noise at the micro electron charge level, thereby allowing to chart substrate

characteristics in terms of trap states or fluctuators modeled by two-level systems (TLSs). Coherent TLSs, qubits, on the other hand, can be employed as spectrometers detecting electromagnetic noise over a large span of frequencies. Qubits as spectrometers provide an excellent means to address the dynamics of impurity spins, which often form the culprit for coherence in quantum nanosystems.

Theoretical overview

For a stochastic process $x(t)$ gated in a time window T , $x(t) \neq 0$ for $|t| < T/2$, the power spectrum $S_x(f)$, representing the spectral resolved ensemble-averaged power of the signal, is independent on T if and only if the stochastic process is stationary. For $1/f$ -like noise the statistical properties change slightly over time scales typically slow relative to the observation times. Thus it is considered a wide-sense (or weakly) stationary process, that is, the correlation functions up to second order are (nearly) invariant for time translation. Then Wiener–Khinchine theorem applies, stating that $S_x(f)$ is given by the unilateral Fourier transform of the autocorrelation function

$$\phi_x(\tau) := \langle \delta x(t + \tau) \delta x(t) \rangle = \int_0^\infty \frac{d\omega}{2\pi} S_x(\omega) \cos(\omega\tau). \quad (2)$$

The integrated power in the spectrum between two frequencies $[f_1, f_2]$ is given by

$$P_x(f_1, f_2) = \int_{f_1}^{f_2} \frac{d\omega}{2\pi} S_x(\omega) = C_x \ln\left(\frac{f_2}{f_1}\right) \quad (3)$$

implying that the integrated power per decade of frequencies is constant, a property known as scale invariance. The autocorrelation function for $\tau = 0$ yields the variance $\langle (\delta x)^2 \rangle$ of the stochastic process which according to Eq. (3) diverges logarithmically both at low and at high-frequencies. This divergence is known as a “paradox” of $1/f$ noise. Of course, the experimentally observed variance is finite since the frequency band for measurements is limited. Indeed it is bounded from below due to the finite duration of the realization of $x(t)$ being measured whose maximum value is set by the overall measurement time t_m . On the other hand, at large frequencies $1/f$ noise becomes much smaller than other contributions to fluctuations and it is not measurable; thus high frequencies are also cut off. This may happen at frequencies ranging from $\sim 10^2$ to $\sim 10^7$ Hz in different systems.

It is worth stressing that there is no experimental evidence for the existence of a low-frequency cutoff f_c . Therefore, strictly speaking the stationarity of the process is still an open question. Difficulties are due to the fact that measuring the low-frequency part of the spectrum, say down to the sub- μ Hz range, would require a duration $t_m \sim 1/f_c$ of weeks. Therefore experimental statistical quantities depend on t_m . In particular this applies to the variance, $\langle (\delta x)^2 \rangle = C_x \ln(f_2 t_m)$, which increases logarithmically with t_m . This is another peculiar property of $1/f$ noise of experimental relevance. In particular, it may have a large impact on applications in coherent nanodevices where large fluctuations produce strong dephasing. From the mathematical point of view, this behavior of statistical quantities implies that $1/f$ -like noise is not strictly stationary; thus it is also nonergodic. On the other hand, the logarithmic dependence on t_m is weak enough to determine weak stationarity allowing the use of the Wiener–Khinchine theorem which relates the power spectra to correlation functions accessed experimentally. These latter show strongly nonexponential behavior decaying logarithmically with time in the important range $f_2^{-1} < t < t_m < f_c^{-1}$, another feature observed in several experiments.

Understanding the microscopic nature of $1/f$ noise is a key problem both from the fundamental point of view and for applications aiming at fabricating improved electronic and coherent devices for modern nanoscience. Typically, models for $1/f$ noise in the solid state are based on a collection of TLSs describing bistable defects or trap states with a wide distribution of tunneling rates (Dutta and Horn, 1981; Kogan, 1996; Weissman, 1988; Koelle et al., 1999; Grasser, 2020). A large collection of such states with broadly distributed parameters generates wide band $1/f$ noise and in what follows we will draw this connection.

Fluctuations of a bistable defect are described by a stochastic process $x_i(t) = \pm 1$ characterized by a single relaxation rate γ_i . Its kinetics leads to RTN where correlations decay exponentially, $\phi_i(\tau) = \exp(-\gamma_i\tau)$, yielding the Lorentzian spectral density

$$S_i(f) = 4 \int_0^\infty d\tau \phi_i(\tau) \cos(2\pi f\tau) = \frac{4\gamma_i}{(2\pi f)^2 + \gamma_i^2}$$

as given by the Wiener–Khinchine theorem. The overall noise is constructed as a linear superposition of these relaxation processes, $x(t) = \sum_i p_i x_i(t)$, and its power spectrum is given by

$$S_x(f) = \sum_i p_i S_i(f) \rightarrow \int_0^\infty d\gamma p(\gamma) \frac{4\gamma}{(2\pi f)^2 + \gamma^2}$$

where we have allowed for a continuous distribution of relaxation rates. Since $\langle (\delta x)^2 \rangle = \int_0^\infty df S_x(f) = \int_0^\infty d\gamma p(\gamma)$, the quantity $p(\gamma) d\gamma$ is the contribution to the variance of processes with rates in the interval $[\gamma, \gamma + d\gamma]$. For a weighting function $p(\gamma) = C_x/\gamma$ in the interval $[\gamma_1, \gamma_2]$ and vanishing elsewhere we obtain

$$S_x(f) = \int_{\gamma_1}^{\gamma_2} \frac{4C_x d\gamma}{(2\pi f)^2 + \gamma^2} = \begin{cases} \text{const} & f \ll \frac{\gamma_1}{2\pi} \\ C_x/f & \frac{\gamma_1}{2\pi} \ll f \ll \frac{\gamma_2}{2\pi} \\ \frac{C_x(\gamma_2 - \gamma_1)}{(\pi f)^2} & \frac{\gamma_2}{2\pi} \ll f \end{cases} \quad (4)$$

Fig. 2 Power spectral density of individual bistable fluctuators (colored solid curves) whose combined effect (black solid curve) yields close to $1/f$ spectrum (indicated by dashed black line). If one of the fluctuators is more strongly coupled (dashed orange) a bump appears in the whole power spectrum (solid orange curve).

reproducing the $1/f$ behavior for intermediate frequencies, $\gamma_1 \ll 2\pi f \ll \gamma_2$ (see Fig. 2). Notice that the extremal rates γ_1 and γ_2 provide soft frequency cutoffs to $S_x(f)$, avoiding the divergence of $\langle (\delta x)^2 \rangle$. They are easily identified for a finite system of discrete fluctuators. We have still to justify the form of $p(\gamma)$ which is the other key assumption determining the $1/f$ behavior of the power spectrum. In the McWhorter model (McWhorter, 1957) for semiconductors, the kinetics is modeled as tunneling processes. The rates have the form $\gamma(z) = \gamma_0 \exp(-z/C)$ depending on the parameter z summarizing the exponential dependence on the width and on the height of the tunnel barriers. Now, if z is distributed uniformly in the interval $[z_2, z_1]$, then $p(\gamma) = C/\gamma$ in $[\gamma(z_1), \gamma(z_2)]$. The same result is obtained if the kinetics stems from thermal activation, $\gamma(E) = \gamma_0 \exp(-E/k_B T)$, assuming that the activation energies E are uniformly distributed as originally proposed by Du Pré and by Van der Ziel (Du Pré, 1950; Van Der Ziel, 1950). Notice that this picture naturally accounts for the weak stationarity (implying nonergodicity) of $1/f$ noise since during the measurement, the TLSs with relaxation rates $\gamma < 1/t_m$ are frozen in some nonequilibrium configuration.

Specific models for $1/f$ noise based on quantum TLSs interacting with phonons (in insulating solids) or electrons (in metals) yielding physically motivated distributions of parameters have been used to explain observed properties of $1/f$ noise. These models apply in rather simple situations of noninteracting impurities while in general, the physical properties of disordered systems depend on their many-body nature. Still, the $1/f$ behavior in the solid-state appears to be a consequence of the universal properties of the kinetics rather than the universality of low-frequency fluctuations (Kogan, 1996).

Finally, we remark that noise from a collection of TLSs is not Gaussian. The Gaussian limit is approached when the noise is generated by a sufficiently large number of independent fluctuators each of which contributes negligibly to the variance. Non-Gaussianity in $1/f$ noise has been observed in different nanosystems, although it poses experimental challenges since it requires finite-bandwidth measurement with large observation times t_m (Weissman, 1988). On the other hand, resolving the contribution of individual fluctuators is needed in view of miniaturization and of the study of the impact of $1/f$ fluctuators on the reliability of quantum architectures. Non-Gaussian features of $1/f$ noise and their impact on phase-coherent quantum systems are discussed in depth in Paladino et al. (2014).

1/f noise in nanoscience

The relative $1/f$ resistance fluctuations $\delta R/R$ have been found to decrease as $1/\text{Volume}$ in bulk materials. Similarly, the relative $1/f$ current noise in FETs has been observed to scale as $\propto 1/\text{Area}$ of the gate electrode. So inevitably, the role of $1/f$ noise will grow when going to nanoscale quantum devices. Lately, nano-scale FETs have been fabricated using heterostructures of atomically thin 2D materials. In such components, the surface-to-volume ratio becomes the largest, which may lead to major issues with the quality of surfaces or interfaces in such nanodevices. As Wolfgang Pauli said “God made the bulk; surfaces were invented by the devil,” this statement becomes more and more relevant when entering the nanoscale regime.

Quantized conductance in nanoscience (mostly 1D or 2D transport) is typically described using the Landauer–Büttiker formalism (Datta, 1997), in which current is given as a sum over transmission channels with transmission τ_{ik} : $I = \sum \tau_{ik} G_0$, where $G_0 = 2e^2/h$ and the indices k and i refer to subbands and quantized states within them, respectively. If we take only one channel with transmission τ , the conductance can be written as $G^{-1} = (1 - \tau)/\tau + G_0^{-1}$, where the first term is the four-terminal resistance and the second term describes the contact resistance for perfect contacts. Since contact resistance is constant, fluctuations in τ yield $\delta R/R = -\delta\tau/\tau$ both for the two- and four-lead resistance R . If the fluctuations in transmission channels are independent, we may add fluctuations of the channels incoherently, which yields $\delta G^2 = \sum \delta\tau_{ik}^2 G_0^2$. Each fluctuating channel can have its own frequency dependence, which in the simplest case is Lorentzian with a cut-off given by a characteristic two-level fluctuator frequency f_{ik}^c (see below). If the cut-off frequencies f_{ik}^c are distributed uniformly on log-scale, summation over all $\delta\tau_{ik}(f)$ yields a $1/f$ noise

spectrum in transmission. In practice, contacts are not ideal and may also have fluctuations. In the nearly ballistic limit, the nonidealities of contacts can be integrated into the transmission values τ_{ik} , and no distinction between scattering in the contact vs. the channel needs to be made.

The conductance in diffusive electrical transport can be written as $G = eN\mu$ where N is the total number of charge carriers and μ is their mobility; e is the electron charge. Therefore, the conductance variation is due to either mobility or carrier number fluctuations:

$$\delta G = eN\delta\mu + e\mu\delta N \quad (5)$$

In bulk metallic conductors, N can be made very large, and the relative fluctuations coming from carrier number can be made to vanish as $1/\sqrt{N}$. However, when the sample size is brought toward the nano regime, the dominance of mobility fluctuations is suppressed and both contributions have to be taken into account. Carrier number is varied by tunneling into trap states that reside in the nearby dielectric, for example in the gate dielectric of a MOSFET transistor. In a small quantum device, such as a quantum point contact (QPC), the trap state may result in distinct RTN signature in the resistance (see Section “Theoretical overview”). The RTN noise in a QPC can be described using Machlup’s formula for a single two-level fluctuator (Machlup, 1954):

$$S_G(f) = [G_{\tau_1} - G_{\tau_2}]^2 \frac{w_1 w_2 \tau}{1 + (2\pi f \tau)^2} \quad (6)$$

where w_1 and $w_2 = 1 - w_1$ denote the probabilities for finding the QPC in conductance states G_{τ_1} and G_{τ_2} , respectively while $1/\tau$ denotes the total transition rate between the conductance states (sum of back and forth rates).

Even though nanoscience devices are small, more than one fluctuator is typically acting on them. The McWhorter model is obtained by considering a collection of single fluctuators which have an equal strength and a uniform distribution of corner frequencies $f_c = 1/(2\pi\tau)$ on logarithmic scale. The resulting $1/f$ spectrum is given in Eq. (4), where $1/\tau$ corresponds to γ .

This $1/f$ spectrum will cover a large frequency span provided that the trap lifetimes $[\tau_1 \dots \tau_2]$ are distributed over a wide range. In the standard McWhorter model, the trapped charge is set to one electron charge e , but with separate TLSs, the charge change in the device induced by the fluctuators may be a fraction of e , which reduces the prefactor C_x in Eq. (4). The McWhorter model has been successfully applied to semiconductor devices and, indeed, good agreement is obtained between experimental results in MOSFETs and the model (Burstein et al., 1957; Grasser, 2020).

Typically, the noise is given as relative fluctuations $(\frac{\delta G}{G})^2 = (\frac{\delta R}{R})^2 = (\frac{\delta N}{N})^2 + (\frac{\delta \mu}{\mu})^2$, that is, scaled by the total conductance of the system. Ideally, the scaling conductance should be ruled by those processes which are governing the fluctuations. Unfortunately, this is not always the case and then the relevant scattering processes should be separated from the data before scaling. Theories can also incorporate correlations between carrier number and mobility fluctuations. The fluctuations are correlated because an electron in the trap state can also modify the scattering governing the mobility of the sample. This is common in 2D material FETs, for example, fabricated using graphene (Balandin, 2013).

Good electrical contacting is difficult to achieve in nanosamples. Consequently, the low-frequency noise formula in Eq. (5) has to be supplemented by the contact noise term, which adds incoherently with the noise arising from the nanodevice. For the relative fluctuations in the total conductance G_T , one obtains then $(\frac{\delta G_T}{G_T})^2 = \frac{R_c^2}{(R + R_c)^2} (\frac{\delta R_c}{R_c})^2 + \frac{R^2}{(R + R_c)^2} (\frac{\delta R}{R})^2$ in which $R = 1/G$ and R_c denote the sample and contact resistance, respectively, and the weighting factor of the relative contact noise $\frac{\delta R_c}{R_c}$ grows with the ratio $\frac{R_c}{(R + R_c)}$.

Both $\delta\mu$ and δN in Eq. (5) may depend on temperature, which can lead to low-frequency conductance fluctuations owing to temperature fluctuations δT (Kogan, 1996). The influence of δT fluctuations is expected to increase in small nanodevices, because $\langle \delta T^2 \rangle \propto k_B T^2 / C$ where C is the heat capacity of the system. These temperature fluctuations can, for example, limit the ultimate energy resolution in nanosized calorimeters, as discussed in Karimi et al. (2020).

TLSs discussed in Section “Theoretical overview” lead to noise and dissipation both in acoustic and electric systems. The acoustic coupling is due to strain fields (elastic dipole moment) that every TLS possesses when embedded into elastic material (Müller et al., 2019). Some of the TLSs possess also an electric dipole moment, which makes them a source of $1/f$ noise in electrical circuits, both for the conductance noise and for fluctuations in dielectric properties of materials (Zmuidzinis, 2012; Müller et al., 2019). Therefore, TLSs make a contribution to the real and imaginary parts of the dielectric constant $\epsilon_{TLS}(f, T)$. In weak electric fields, the loss tangent $\delta_{TLS}(f, T)$ of the dielectric constant is dominated by TLS energies close to hf :

$$\delta_{TLS}(f, T) = \frac{\Im \epsilon_{TLS}(f, T)}{\Re \epsilon} = \delta_0 \tanh\left(\frac{hf}{2k_B T}\right) \quad (7)$$

where the hyperbolic tangent describes the equilibrium population difference of the two levels and δ_0 is the intrinsic loss parameter proportional to the density of TLS per unit volume and energy. If the asymmetry and tunneling parameters of two-level states are uniformly distributed in energy as assumed in the standard tunneling model (Müller et al., 2019), the low-temperature loss tangent becomes independent of frequency. In the limit $k_B T \gg hf$, the upper state will become populated, leading to $\delta_{TLS}(f, T) \propto hf/k_B T$. Clearly, the role of TLSs in dissipation vanishes when $f \rightarrow 0$. According to Kramers–Kronig relations, Eq. (7) can be utilized to obtain the reactive part of $\epsilon_{TLS}(f, T)$, and the equations for fluctuations of reactance (capacitance) can be derived (Zmuidzinis, 2012).

The capacitance modulation due to TLSs provides an efficient means to investigate two-level fluctuators and the ensuing $1/f$ noise using superconducting microwave cavities (Zmuidzinis, 2012; Müller et al., 2019; Wang et al., 2020). Furthermore, understanding the performance limits of such cavities is vital because high-quality superconducting microwave cavities are critical elements for efficient qubit readout (Blais et al., 2021) and kinetic inductance detectors for sensitive bolometry or single photon detection (Ulbricht et al., 2021). A summary of recent results obtained for the loss tangent is given in Wang et al. (2020) for several

dielectric and superconducting materials that are relevant for coherent quantum nanoscience. Most recently, promising results have been obtained for superconducting tantalum (Place et al., 2021); in comparison to Nb, this is assigned to more kinetically limited and chemically robust oxides in Ta (de Leon et al., 2021).

Measurement power is known to modify the influence of TLSs (Wang et al., 2020). Dissipation in a superconducting material is first governed by TLSs, but increasing power leads to the creation of quasiparticles that dominate losses at high rf power. On the other hand, when there are spatial variations in the superconducting order parameter, that is, the superconducting gap, it is possible to have quasiparticles trapped into local minima of this gap variation. In fact, TLSs due to trapped quasiparticles on the surface of Al superconductor have been observed to produce low-energy TLSs up to energies of $\hbar \times 20$ GHz (de Graaf et al., 2020). The observed-level separation agrees with theoretical values obtained using estimates of the second derivative of the spatial variation of the gap (de Graaf et al., 2020).

In standard TLS models, the number of two-level states N is evenly distributed in energy, that is, the density of states $\mathfrak{N}(E) = dN/dE = \text{const.}$ Plenty of experiments have been performed to test this hypothesis (Dutta and Horn, 1981). In quantum nanodevices, there are recent experiments that indicate an energy-dependent density of states $\mathfrak{N}(E)$ (Müller et al., 2019). Energy dependence can arise for example from interactions between TLSs, which yields an Efros-Shklovskii type of pseudogap at small energies. There are indications that $\mathfrak{N}(E) \propto E^{\alpha/2}$ with $\alpha \sim 0.2\text{--}0.7$; the same exponent appears also in the temperature dependence of 1/f noise $S_V \propto 1/T^\alpha$ (Burnett et al., 2014; Müller et al., 2019), which leads to increase of 1/f noise with decreasing T .

Surface spins, such as physisorbed atomic hydrogen, have been found to behave as TLSs that cause significant dielectric and flux noise. Removal of surface adsorbants by suitable physical or chemical treatment has led to a factor of 10 reduction in frequency fluctuations of a microwave cavity at ~ 5 GHz frequency (de Graaf et al., 2018). The scaling of 1/f as $\propto \text{Area}$ is quite conspicuous in superconducting quantum nanoscience, for example in the superconducting loops SQUIDs (Superconducting Quantum Interference Devices, see Section “Noise in quantum circuits”). It is also becoming apparent that surfaces and interfaces impose large noise contributions in superconducting microwave circuits, which may even dominate the defect/impurity contributions scaling with volume.

Besides TLSs, nonequilibrium quasiparticles may cause excess noise and losses in superconductors. In general, the number of quasiparticles observed in superconducting films at $T \lesssim 150$ mK amounts to $10^{-8} \dots 10^{-6}$ per Cooper pair, which is clearly larger than predicted from the BCS theory for a superconductor in equilibrium with the environment at $T = 10$ mK. The reason for excess quasiparticles is not fully resolved yet, but recent experiments have indicated that nonequilibrium phonons, created by, for example, cosmic rays, do play an essential role in the process (McEwen et al., 2022).

Noise in quantum circuits

Quantum circuits are based on two canonically conjugate variables, charge Q and flux Φ (see Section “Artificial atoms”). The strength of quantum fluctuations in these variables depends on the impedance of the quantum circuit Z_0 . If Z_0 is large (fluctuations for the impedance $Z_0 = \sqrt{L/C}$ are derived from corresponding LC oscillator, Devoret, 1995), the fluctuations of charge are given at the quantum limit by $\langle \delta Q^2 \rangle = \frac{\hbar}{2Z_0}$ while the fluctuations for flux amount to $\langle \delta \Phi^2 \rangle = \frac{\hbar Z_0}{2}$. Hence, quantum circuits at large Z_0 are susceptible to external charge noise while external flux noise is detrimental in the case of small Z_0 .

Flux noise is produced by resistance fluctuations when current is passed through a normal conductor. In metallic conductors, the commonly accepted view is that 1/f noise is determined entirely by fluctuations in charge carrier mobility (Hooge et al., 1981). In addition to models based on localized states and fluctuating scattering cross sections (Hooge, 1994), there are more refined models based on a modification of electronic wave interference induced by a defect displacement by a hopping event. These models, the universal conductance fluctuation noise and local interference noise model, have been quite successful in accounting for many experimental observations in metals with defects as summarized in Giordano (1989).

Superconducting quantum interference devices

Classical SQUIDs are inherently low impedance devices, which is highlighted by the small shunt resistance inserted in them for stabilization of their phase dynamics. Hence, their ultimate sensitivity is limited by the low-frequency flux noise, or alternatively by internal fluctuations of the Josephson energy of the tunnel barriers. Low-frequency noise in SQUIDs displays distinct $1/f^\alpha$ behavior (Wellstood et al., 1987; Cantor and Koelle, 2004). In spite of 50 years of investigations, the origin of flux noise in SQUIDs is still poorly understood. It has been found that its power law exponent α varies substantially around $\alpha = 1$, and the exponent displays strong temperature dependence (Anton et al., 2013). An increase of noise linear with the area of the superconductor in the SQUID loop has been found (Anton et al., 2013), but no clear correlations have been observed neither on the selection of materials nor on the details of the device geometry. Even though the fundamental mechanism for flux noise in SQUIDs remains unclear, there are plenty of experiments indicating that impurity atoms with a spin magnetic moment are involved in the noise phenomena.

Flux noise in a SQUID may originate from paramagnetic impurities residing on the superconducting material of the SQUID loop. Paramagnetic impurities produce flux according to paramagnetic susceptibility $\chi(T) \propto 1/T$, the fluctuation of which produces flux noise. Such fluctuating paramagnetic impurities have been observed in Al, Nb, Au, Re, and Ag among others (Sendelbach et al., 2008; Bluhm et al., 2009). The fluctuating spins are believed to reside on the metal surface as the flux noise scales with the surface area of the SQUID loop (Anton et al., 2013). In order to obtain a correct order of magnitude of flux noise, one has to assume a magnetic impurity concentration of $\sim 1 \times 10^{18}/\text{m}^2$ with an impurity moment of one Bohr magneton, given by electron rest mass m_e and electron charge e as $\mu_B = \frac{e\hbar}{2m_e} = 9.274 \times 10^{-24}$ J/T, that is, a distance of 1 nm between the impurities (Sendelbach et al., 2008).

There is also experimental evidence for adsorbed oxygen molecules producing a magnetic signature and flux noise (Kumar et al., 2016). With its paramagnetism, oxygen can meet the above-stated requirement for strength and density of impurity moments.

Hydrogen atoms provide an alternate source for flux noise (De Graaf et al., 2017; Quintana et al., 2017). Electron spin resonance measurements on sapphire have revealed a resonance with a 1.42 GHz line splitting which matches free H atoms. In addition, flux noise measurements using the qubit relaxation rate indicate a peak at 1.4 GHz. Further support for the presence of H is provided by DFT calculations of interstitial hydrogen atoms embedded in bulk sapphire, which yield an ESR splitting of 1.28–1.36 GHz (Wang et al., 2018). Recently, complex radicals have also been found to contribute to the noise and decoherence phenomena (Un et al., 2022).

Single electron tunneling devices

The most sensitive charge detectors in the solid state are single electron transistors (SETs) and charge qubits. Both devices suffer strongly from background charge fluctuations which often have 1/f character with some overlying Lorentzian spectra due to strongly coupled TLSs (Paladino et al., 2014). Using Al/AlO_x/Al tunnel barriers on top of common dielectric such as Si, SiO₂, and Si₃N₄, the charge noise amounts to $10^{-4} - 10^{-3} e/\sqrt{\text{Hz}}$ at 10 Hz, both in superconducting and normal metal regimes. The best Al/AlO_x/Al devices using stacked design have reached $8 \times 10^{-6} e/\sqrt{\text{Hz}}$ at 10 Hz (Krupenin et al., 2000). Charge noise in SETs arises typically from charged two level states capacitively coupled to the island (Paladino et al., 2014). Such TLSs are present in all back-gated devices at the interface of the gate dielectric and the conducting materials. The best charge sensitivities in Al-based devices have been obtained in structures where the contact area to dielectric substrate material has been eliminated with a stacked design (Krupenin et al., 2000). The achieved levels of charge noise have not been adequate for fabricating well-functioning charge qubits, that is, Cooper pair boxes, using Al technology (Astafiev et al., 2006; Paladino et al., 2014).

1/f charge noise is a very important characteristic for industrially fabricated silicon quantum dot MOSFET devices which are being developed for spin qubits (Harvey, 2022). Typical noise values in multielectron quantum dots at 1 Hz are in the range $1 - 10 \mu\text{V}$ referred to the gate electrode (Petit et al., 2018; Zwerver et al., 2022) (corresponding to $80 - 800 \mu\text{e}/\sqrt{\text{Hz}}$ using a gate capacitance 10^{-17} F). Small charge noise in these quantum dots is important both for the coherence and read-out of spin qubits (Stano and Loss, 2022).

In 1D and 2D nanodevices, the density of states can be strongly energy dependent. This causes fluctuations in the chemical potential μ_F to generate carrier number fluctuations, which leads to a one-to-one correspondence between the conductance noise spectrum and the frequency spectrum of μ_F fluctuations. The fluctuations in μ_F may be induced, for example, by chemical doping or background charge fluctuations (Pellegrino et al., 2019). Such fluctuations in 1D and 2D conductors are similar to Coulomb effects, where the shift of chemical potential is given in terms of variation in the island charge $Q = Q_i$. The influence of Q_i on the current I can be described using transconductance $g_m = \partial I / \partial V_g = C_{\text{eff}} \partial I / \partial Q_i$ where C_{eff} specifies the connection of the island charge to the shift of electrochemical potential. Typical charge noise values for carbon nanotube (Roschier et al., 2001; Vitusevich et al., 2011) and 2D material devices (Karnatak et al., 2017) with good transconductance are in the range $4 \times 10^{-5} \dots 10^{-3} e/\sqrt{\text{Hz}}$ at 10 Hz.

Besides charged TLSs, background fluctuations can arise from charge localized at interfaces where it can be transported by impurities or defects easier than within the bulk. This calls for extreme care when stacking 2D heterostructures in order to keep their 1/f noise as small (Balandin, 2013; Karnatak et al., 2017). In addition, there has been a substantial effort in studies on suspended 2D materials, in particular, graphene, which has been employed as a low-noise platform for investigations of noise induced by diffusion of mobile scattering centers on the membrane (Kamada et al., 2021). As an interpretation of the observed noise results, intrinsic long-term correlations due to clustering and declustering of adsorbed atoms have been proposed (Kamada et al., 2021). Interactions between TLSs and non-Gaussian fluctuations can also be investigated by the second spectrum (Pellegrino et al., 2023; Zeng et al. (2023) and references therein).

1/f Noise in quantum-coherent nanodevices

Nanoscale-based quantum technologies build on harnessing fundamental properties of quantum states, such as superposition, quantum coherence, and entanglement to enable novel functionalities (Heinrich et al., 2021). The extraordinary impetus in quantum technology research, from academia to spin-offs and industries, since the last few years of the 20th century has led to a number of breakthroughs. At the same time, it has been pointed out that fluctuations characterized by power spectral density $1/f^\alpha$ with $\alpha \approx 1$ in a setup-dependent low-frequency range are paramount in most of the coherent nanodevices. On one side, they limit the ability to control the quantum-coherent behavior of engineered nanostructures, leading to a gradual loss of phase coherent evolution or *decoherence*. On the other side, the systematic analysis of decoherence under different control sequences allows for reconstructing the frequency spectrum of stochastic signals, a task commonly referred to as *noise spectroscopy*. Here we present an overview on how fluctuations with 1/f spectrum influence the phase coherent evolution of artificial atoms playing the twofold roles of elementary quantum bits and of quantum sensors, in particular of noise spectrometers. We will refer to selected paradigmatic examples of coherent nanodevices.

Artificial atoms

Nowadays micro and nano solid-state devices can be fabricated. They are called *artificial atoms* (AAs) (Buluta et al., 2011) since they show functional analogies with natural atomic or molecular systems.

Fig. 3 (A) The rf-SQUID is a superconducting ring with inductance L , and associated energy $E_L = \Phi_0^2/L$, interrupted by a Josephson junction with critical current I_c , Josephson energy $E_J = 2e I_c / \hbar$ and capacitance C ; several noise sources may affect its dynamics, many of them displaying a $1/f$ low-frequency behavior. (B) The equivalent circuit of the rf-SQUID, the flux Φ_x being induced by a current I_x flowing in a nearby circuit. (C) The rf-SQUID potential $U(X)$ Eq. (8): the device is analogous to a particle of “mass” C moving in this potential, modulable by varying Φ_x . (D) Equivalent circuit of the Cooper-pair box, where a discrete-valued charge $\hat{Q}$ is stored in a superconducting island (red) connected to the circuit by a Josephson junction and modulated by the external voltage V_x via a gate capacitance C_x .

Electrons in semiconductors can be confined in a “box” called *quantum dot*, small enough that they do not behave as in bulk solids but rather as electrons in individual atoms. Indeed they have a discrete spectrum of energy and at low temperatures, electrons can occupy only the lowest energy levels. A qubit can be encoded in the charge or the spin of electronic configurations. Spin qubits couple weakly to their environment and leveraging on the available fabrication technologies they are interesting candidates for building large-scale quantum computers.

Superconducting artificial atoms are devices made of tunnel junctions displaying the Josephson effect. In a superconductor, the many-body condensate is described by a single-particle wavefunction, and in coherent devices, its phase behaves as a quantum degree of freedom analogous to the coordinate of a fictitious particle in a confining potential. Superconducting AAs may encode a qubit in the eigenstates of the potential (phase qubits), in the flux enclosed in a superconducting quantum interference device (SQUID) ring (flux qubit), in the extra charge stored in a superconducting “box” (charge qubits) to mention the simplest instances (see Fig. 3).

As an example, the rf-SQUID illustrated in Fig. 3A is modeled by an equivalent circuit with concentrated elements (Fig. 3B). The circuit’s dynamics emulates a particle moving in the potential

$$U(X) = -E_J \cos\left(\frac{2\pi X}{\Phi_0}\right) + \frac{E_L}{2} \left(\frac{X - \Phi_x}{\Phi_0}\right)^2 \quad (8)$$

where the “coordinate” X is the total magnetic flux concatenated with the ring Φ_T and the “momentum” P is the charge Q accumulated at the surface of the junction’s electrodes. The Hamiltonian describing the quantum-coherent regime is obtained by quantizing the canonical coordinates, which become noncommuting operators, $[\hat{Q}, \hat{\Phi}_T] = i\hbar$. Here Φ_x is the flux of an external bias field concatenated to the ring, $\Phi_0 = h/(2e) \approx 2.068833 \times 10^{-15}$ Wb is a universal constant named *flux quantum* and other circuit parameters are defined in Fig. 3.

In principle, an rf-SQUID biased by an external flux $\Phi_x \approx \Phi_0/2$ may function as a qubit. In this case $U(X)$ is a nearly symmetric double-well potential (see Fig. 3C) with a low-energy spectrum consisting of a doublet. The qubit Hamiltonian is obtained by truncating the system to these two levels. In the spin language, it is written as

$$\hat{H} = -\frac{\varepsilon(\Phi_x)}{2} \sigma_z - \frac{\Delta}{2} \sigma_x \quad (9)$$

where ε is the asymmetry of the potential, modulable by Φ_x and Δ is a tunneling matrix element between its minima. The two eigenvalues of σ_z correspond to states localized in one of the minima of the potential, the total concatenated flux being $\Phi_T = 0, \Phi_0$. These are the basic principles of the so-called flux-qubit whose actual design is a multijunction version of the rf-SQUID (Krantz et al., 2019).

Classical noise induces fluctuation of the parameters. For instance, flux noise is described by adding a stochastic external flux, $\Phi_x \rightarrow \Phi_x + \tilde{\Phi}_x(t)$, which induces fluctuations $\tilde{\varepsilon}(t)$ of the potential asymmetry, as illustrated in Fig. 3C. Instead, fluctuations of E_J due for instance to the impurities in the Josephson junction induce fluctuations of the barrier height $\tilde{U}_0$ of the potential and in turn fluctuations $\tilde{\Delta}(t)$ of the tunnel splitting. In general, the Hamiltonian acquires a fluctuating term $\delta\hat{H}(t) = -\frac{1}{2}[\tilde{\varepsilon}(t) \sigma_z + \tilde{\Delta}(t) \sigma_x]$, where $\tilde{\varepsilon}(t)$ and $\tilde{\Delta}(t)$ are classical stochastic processes. Experiments show that all of them exhibit $\sim 1/f$ behavior at low frequencies (Paladino et al., 2014; Bylander et al., 2011). The approach outlined for classical noise may be extended to describe phenomenologically quantum noise. In this case, the stochastic processes are substituted by operators describing physical fields exerted by the microscopic quantum degrees of freedom of one or more physical environments (Paladino et al., 2014).

The other prominent family of superconducting qubits, including the transmon (Koch et al., 2007), which provides the forefront device for present superconducting quantum processors (Arute et al., 2019; Jurcevic et al., 2021; Wu et al., 2021), may be introduced following the same roadmap. The simplest instance is the so-called charge qubit, Fig. 3D (Nakamura et al., 1999), where the conjugate variables are the discrete charge $\hat{Q}$ into the superconducting island and the cyclic coordinate $\hat{\Phi} = \hbar\hat{\phi}/(2e)$ related to the quantized phase difference ϕ between the macroscopic wave functions of the electrodes of the Josephson junction. Again the Hamiltonian can be written in Eq. (9) where now fluctuations $\tilde{\varepsilon}$ are related to charge noise, whereas $\tilde{\Delta}(t)$ originates from fluctuations of E_J or from flux noise.

The main effect of low-frequency noise on the dynamics of the qubit is dephasing. For instance, the populations of the eigenstates of an isolated qubit with Hamiltonian Eq. (9) undergo coherent oscillations with the angular frequency given by the qubit energy splitting (we take $\hbar = 1$) $\Omega = \sqrt{\varepsilon^2 + \Delta^2}$. Due to the coupling to the environment, which induces fluctuations of Ω , the amplitude of coherent oscillations decays as $A(t) = e^{-\Gamma(t)}$. Dephasing strongly depends on how the qubit is biased or manipulated. This extreme sensitivity is exploited to mitigate dephasing or, on the contrary, for quantum sensing of environmental noise. For instance, let's set the flux bias such that $\varepsilon(\Phi_x) = 0$ and consider the effect of fluctuations $\tilde{\Delta}$ (called "longitudinal"). Then the decay of oscillations is given by

$$\Gamma(t) = \frac{t^2}{2} \int_{t_m}^{\infty} df \mathcal{F}_0(f) S_{\Delta}(f) \quad (10)$$

being determined by the power spectrum of the fluctuations of $\tilde{\Delta}(t)$ "filtered" by the function $\mathcal{F}_0(x) = \sin^2(\pi x)/(\pi x)^2$. Longitudinal 1/f noise may determine a very strong decay $\Gamma(t) \approx \frac{1}{2} \langle (\delta\tilde{\Delta})^2 \rangle t^2$, where $\langle (\delta\tilde{\Delta})^2 \rangle \sim \int_{1/t_m}^{f_2} df C_{\Delta}/f \approx C_{\Delta} \log(f_2 t_m)$. This strong decay of coherences determines the complete phase randomization in a generic solid-state system at equilibrium. Instead, $\tilde{\varepsilon}$ noise (called "transverse") contributes at second order on the fluctuations of the qubit splitting Δ , thus their impact is more limited resulting in a power-law decay

$$\Gamma(t) = \frac{1}{4} \ln \left[1 + \left(\frac{\langle (\delta\tilde{\varepsilon})^2 \rangle t}{\Delta} \right)^2 \right] \quad (11)$$

Therefore, to reduce the impact of low-frequency noise, an optimal bias strategy has been used, where the qubit is biased in such a way that the main source of noise is transverse. This way, the impact of flux (charge) noise in flux (Cooper-pair box-based) qubits is minimized.

In the last generation of qubits, significant coherence times are achieved by designing the device in a way that protection from noise is stronger for a larger range of parameters. For instance, dynamical sweet spots based on the application of periodic drives have been identified (Huang et al., 2021), demonstrating reduced susceptibility to low-frequency noise and predicting an enhancement of pure dephasing by 3 orders of magnitude in the fluxonium (Nguyen et al., 2019). For a recent review on noise-protected superconducting quantum circuits, we refer the reader to Gyenis et al. (2021). Here we mention that, in addition to design strategies, considerable advances in materials science and engineering materials provided significant noise protection, as discussed in de Leon et al. (2021).

In general, amorphous or glassy materials with plenty of TLSs may be disadvantageous in coherent quantum devices. Besides residing in the tunnel barrier material, TLSs may influence the dielectric constant of substrates as well as insulating coatings between wiring layers. The inverse time constants of the two-level states have been found to range from mHz to GHz frequencies. Hence, in addition to limiting the quality factors of qubits, TLSs can influence readout resonators for qubits at GHz frequencies as well as low-frequency SQUID magnetometers, as discussed in the next paragraph.

Defects in oxides and interfaces also represent the main limitation of gate fidelities in semiconductor-based quantum dot charge qubits, where they cause voltage fluctuations on the control electrodes. Analogously to superconducting qubits, dephasing due to 1/f-charge noise is minimized by working at sweet spots (Petersson et al., 2010; Dial et al., 2013; Thorggrimsson et al., 2017; Scarlino et al., 2019; Yang et al., 2019; Kratochwil et al., 2021). Spin-based quantum dot qubits (Loss and DiVincenzo, 1998) in semiconductors are sensitive to magnetic field noise due to the surrounding nuclear spin bath and to charge noise. Recent progress in this field has been discussed in Harvey (2022) and Laucht et al. (2021).

Quantum sensing

Coherent nanosystems are at the core of investigation also in the recent field of quantum sensing. For a recent review, we refer the reader to Degen et al. (2017) and references therein. The idea behind is to turn into an exploitable property the sensitivity to external disturbances representing an intrinsic weakness for quantum computing purposes. Quantized energy levels, quantum coherent evolution, or quantum entanglement are used to measure a physical quantity or to improve sensitivity beyond classical measurements. To function as quantum sensors, physical systems need to satisfy the DiVincenzo criteria of efficient initialization and coherent manipulation (DiVincenzo, 2000). In addition, they have to interact with the physical quantity to be detected $V(t)$, which leads to shifts of the quantized energy levels or splitting, $E(V)$. The relevant quantity is the transduction parameter $\gamma = \partial^q E / \partial V^q$, where usually $q = 1$ or $q = 2$. In any physical implementation, the sensitivity to external signals carries also coupling with unwanted external noise sources. The trade-off between strong coupling to the quantity to be detected and weak disruptive noise effects is quantified by the sensitivity which scales as $\propto 1/(\gamma\sqrt{T})$, where T is the relevant decoherence or relaxation time (Degen et al., 2017).

Quantum sensors require maximal transduction and long decoherence time. In general, the role of $1/f$ noise in these schemes is that of limiting the coherence time which governs the measurement time available for quantum sensing. Thus, lowering the amount of $1/f$ noise will increase the sensitivity and consequently also the dynamic range of quantum sensing (the largest signal is set by the smallest measurement time).

The effect of low-frequency fluctuations can be illustrated in nitrogen-vacancy (NV) centers in diamond (Doherty et al., 2013), one of the most advanced platforms for quantum sensing. The use of electron spin states of NV centers in diamond for highly sensitive magnetometry is an established fact with relevant applications. For an in-depth description of this topic, we refer to Rondin et al. (2014), Schirhagl et al. (2014), and Rembold et al. (2020). Key properties of these color centers are the possibility to optically initialize, read out, and coherently manipulate at ambient conditions. The sensing protocol is essentially the measurement of the Zeeman splitting induced by an external magnetic field. For advanced sensing applications, the transition frequency is detected via interferometric techniques. The basis of these techniques is Ramsey interference, the spin equivalent of an optical Mach–Zehnder interferometer. The qubit is prepared in the superposition $|0\rangle + e^{i\phi_0}|1\rangle$, and Ramsey interference is based on the phase accumulated by the Larmor precession during the interrogation time. This phase is related to the addressed transition frequency, which depends on the external field to be measured. This allows the detection of static, slowly varying, or broadband near-DC signals. The main limitation of DC magnetometry with NV centers is dephasing due to slowly varying inhomogeneities of the dipolar fields due to unpolarized spin impurities in the diamond crystal, mostly ^{13}C and ^{14}N .

Dynamical decoupling (DD) schemes inspired by NMR (Becker, 2000) have been used to reduce the effect of low-frequency noise components (Paladino et al., 2014). These techniques are by now routinely employed as active control tools for increasing the quality factors of quantum gates and in quantum sensors. The simplest instance is Hahn's echo, consisting of a π -pulse applied halfway of the detection in such a way as to reverse the qubit evolution so that the phases accumulated in the two-time intervals cancel out.

DD refers to sequences of multiple π -pulses which allow shaping of the frequency response of the quantum sensor, in particular attaining higher sensitivity when measuring AC magnetic fields and longer coherence times for quantum bits and gates.

The DD control protocol is conveniently formulated in terms of filter functions entering the qubit coherent oscillations, analogously to Eqs. (10) and (11). For Gaussian noise coupled longitudinally, the filter function takes the form (Uhrig, 2007)

$$\mathcal{F}_N(f, t) = \frac{1}{(2\pi ft)^2} \left| 1 + (-1)^{N+1} e^{i2\pi ft} + 2 \sum_{j=1}^N (-1)^j e^{i2\pi ft_j} \right|^2. \quad (12)$$

N is the number of pulses applied at time t_j within the measurement time, t , perpendicularly with respect to the qubit quantization axis. A variety of pulse sequences have been investigated, differentiated by pulse directions and timings. The resulting filters effectively eliminate from the qubit evolution spectral noise components to different degrees (see Fig. 4C). For instance, the Carr–Purcell sequence (Carr and Purcell, 1954), which consists of n equidistant π pulses, acts as a narrow quasi-monochromatic and tunable filter. The first pulse time, t_1 selects the pass-band frequency while n determines the filter width. The CP sequences allow the detection of monochromatic AC fields with periodicity commensurate with the $2t_1$, the interpulse timing. In NV sensor settings, periodic protocols have been exploited to detect and characterize individual ^{13}C nuclear spins placed a few nanometers apart from the NV center (Zhao et al., 2012; Taminiau et al., 2012).

Fig. 4 (A) In the spin language, a pure state of a qubit is a unit vector of the Bloch sphere and the qubit Hamiltonian Eq. (9) is represented by a vector $\vec{H}$. Coherent oscillations correspond to a precession of the state vector about $\vec{H}$, whose direction and modulus fluctuate due to noise, affecting the qubit dynamics. (B) Coherent oscillations of the qubit populations in an isolated system (gray line) are strongly suppressed by longitudinal low-frequency noise (blue line), while the effect of transverse noise (red line) is much weaker. (C) Frequencies of the $1/f$ spectrum (gray lines, the thick one for a finite low-frequency cutoff) entering dephasing are filtered by the qubit dynamics: the blue curves represent $F_0(f)$ entering Eq. (10) at different times, larger t yielding smaller bandwidths. The orange, magenta, and green curves represent the action of the filter Eq. (12) for periodic dynamical decoupling (DD) operated by $N\pi$ -pulses, $N = 2$ representing spin echo; the bandwidth migrates to larger frequencies suppressing the effect of low-frequency noise.

Despite the extraordinary progress, the sensitivities currently achieved are lower than the theoretical limits established by the qubits' lifetimes. Material synthesis techniques have been developed to reduce paramagnetic impurities and strain effects in the host crystal. In addition, quantum optimal control (QOC) methods have been applied to quantum sensors (Giovannetti et al., 2011; Rembold et al., 2020; Hernández-Gómez and Fabbri, 2021). These techniques represent an alternative route to enhance the coherence time when noise at high-frequencies dominates.

Noise spectroscopy

Noise spectroscopy is an important tool in quantum sensing. The term refers to methods for reconstructing the frequency spectrum of stochastic signals. The most common tools are based on Ramsey interferometry or more involved rf pulse sequences (Degen et al., 2017). Noise spectroscopy can provide relevant information both on the signal to be detected and on the intrinsic noise of the sensor. It can be formulated again in terms of filter functions. In fact, in addition to the decoupling regime, there exist spectral regions of the filters of positive gain. The effect of the corresponding spectral components of noise is amplified (Paladino et al., 2014).

Noise spectroscopy is routinely used as a powerful tool to characterize $1/f$ charge and magnetic flux noise in superconducting qubits. Here we only mention some recent results in this platform. Exploiting the narrow-band filtering properties of the Carr Purcell Meibum Gill (CPMG) sequence (Meiboom and Gill, 1958), Bylander et al. (2011) measured flux noise in a persistent current qubit away from the optimal point in the spectral region 0.2–20 MHz, where $1/f^{0.9}$ noise was detected. The decay of Rabi oscillations provided an independent measurement of the noise spectrum at frequencies of the order of $\Omega_{\text{Rabi}} \approx$ MHz. Remarkably, the same power law behavior has been detected by Ramsey interferometry in the much lower frequency range 0.01–100 Hz in Yan et al. (2012). By studying the decay of Rabi oscillations under strong driving conditions, Yoshihara et al. (2014) inferred flux noise up to 1.7 GHz. Around 300 MHz, a spectrum close to $1/f$ was detected where evidence of a Lorentzian component, possibly due to a more strongly coupled fluctuator was pointed out, see Fig. 2. The result of these types of measurements is sketched in Fig. 1. Most noise spectroscopy protocols have been developed tailored to Gaussian noise models. Norris and Viola (Norris et al., 2016) introduced a noise spectroscopy protocol allowing for higher order spectral estimation of non-Gaussian noise, as demonstrated in a flux-tunable superconducting qubit sensor (Sung et al., 2019). This represents a valuable tool for characterizing discrete microscopic sources with a $1/f$ spectrum. More recently, multilevel noise spectroscopy has been realized via a spin-locking-based protocol (Sung et al., 2021). The additional information gained from probing the higher excited levels enabled the identification of contributions from different underlying noise mechanisms in a flux-tunable transmon qubit. Noise spectroscopy tracking multilevel fluctuations represents also an efficient tool for materials characterization, as it has been demonstrated in a transmon fabricated with tantalum metal (Tennant et al., 2022).

Silicon quantum dot spin qubits have also been employed as metrological devices to study the noise environment experienced by the qubit. Noise spectroscopy has been done for an implanted phosphorus donor qubit in silicon (Si:P) (Muhonen et al., 2014) and a SiGe quantum dot spin qubit (Yoneda et al., 2017). Charge noise spectroscopy in an isotopically purified electron spin qubit in a $^{28}\text{Si}/\text{SiGe}$ quantum dot has been realized by an independent estimate of $S(f)$ around 0.01–1 Hz by Ramsey interferometry, and around tens of kilohertz by CPMG sequence. Remarkably, the two estimates are consistent with $1/f^{1.01}$ spectrum extending over seven decades of frequencies (Yoneda et al., 2017). In this experiment, rapid spin rotations are applied by using a proximal micromagnet, which induces spin-electric coupling fields. In Chan et al. (2018), the environment of a silicon metal–oxide–semiconductor (SiMOS) quantum dot spin qubit has been characterized via CPMG DD pulse sequences. The detected charge noise is $1/f^\alpha$ with $\alpha \approx 0.8$ –1 for frequencies between 2 and 20 kHz. Noise in the energy splitting of an electron spin qubit in a highly isotopically purified $^{28}\text{Si}/\text{SiGe}$ device has been detected via Ramsey spectroscopy down to 10^{-5} Hz and by Hanh-echo at higher frequencies in Struck et al. (2020). Measurements revealed a $1/f^2$ behavior below 5×10^{-3} Hz followed by $1/f$ trend. These dependencies have been found to be consistent over 8 decades with charge noise independently detected in the same setup via measurement the current noise of a nearby SET sensor.

Conclusion

It is widely recognized that the road to avoiding $1/f$ noise in nanodevices is to improve the characteristics of the employed materials. Silicon crystal growth technology has been perfected in the past, and nowadays extremely pure silicon single crystals are available. Similar quality of materials would be required for various substances that are employed in quantum technology (de Leon et al., 2021). One possible route for achieving high-quality materials is to tailor devices atom by atom (Khajetoorians et al., 2019). The era of such a “designer matter” approach has recently begun, but plenty of work lies ahead before the quality and throughput of these materials will become relevant for alleviating $1/f$ noise in mainstream quantum science and technology.

Progress in the more regular “engineered matter” is being made using composite, hybrid materials, for example, encapsulated graphene with superconducting contacts (Wang et al., 2019). Such hybrid junctions have been employed in superconducting qubits, but it appears that there is still substantial $1/f$ noise present at the interfaces (Haque et al., 2021). In addition, different mechanisms may originate critical current fluctuations, for instance, charge carrier density fluctuations might also play a role (Pellegrino et al., 2020). The resistance noise properties of regular AlO_x tunnel junctions are still superior, and the influence of their E_J (or critical current, I_c) noise on qubit coherence time is small. It will become essential when the coherence time will be in the ms range (Siddiqi, 2021).

One of the emerging, striking fields of 2D materials is the magic angle twisted bilayer graphene (MATBG), in which superconductivity (Cao et al., 2018) is assigned to flat energy bands (Kerelsky et al., 2019; Xie et al., 2019; Törmä et al., 2022). The MATBG samples can be tuned between superconductivity and Mott insulating states with a rather small change in the charge carrier density. However, owing to variations in local charge doping or in twist angle, the superconducting properties of these samples may fluctuate in space or time, and thus display $1/f$ noise in critical current. A study of such noise will establish the quality of this material for certain sensitive detector applications, for example, their use in kinetic inductance detectors for radiation.

2D materials offer a platform for the miniaturization of components for coherent quantum circuits (Antony et al., 2021; Wang et al., 2022). Large, low-loss capacitance per unit area can be achieved using a few layer hBN as an insulating layer. Furthermore, by utilizing h-BN as a gate dielectric, strong gate coupling for FETs can be obtained. Compared with amorphous hafnium oxide, the TLS density of h-BN dielectric is definitely smaller, which promises smaller $1/f$ noise for components in such 2D material technology.

With the increasing miniaturization of electronic quantum components, the relative magnitude of $1/f$ noise has been constantly growing over the years as the active part of the component is influenced strongly by one single impurity. Similar extreme purity as for single silicon crystals would be needed for other technologically relevant materials in the future (de Leon et al., 2021). An alternative solution to the $1/f$ noise dilemma is to harness independent single atoms or molecules (Yu et al., 2021) as building blocks for quantum components and sensors. This has already been achieved quite well in quantum sensors based on NV centers in diamond or in optically read magnetometers based on rubidium gas for example (Aslam et al., 2023).

Besides DD schemes, the use of limited quantum resources can be bolstered by using phase estimation algorithms (Kitaev, 1995). These algorithms provide a sensitivity improvement directly proportional to the measurement time, that is, they allow to achieve the Heisenberg limit in measurement accuracy. Combined with Bayesian learning algorithms, phase estimation schemes may provide ultimate speed for high-sensitivity sensing, for example, magnetometry (Bonato et al., 2016), in spite of the influence of $1/f$ noise embedded in the coherence time of the sensing qubit.

QOC is another promising methodology both for sensing applications and for quantum computation applications which require high-fidelity gate operation. One instance where QOC can provide a solution is in reducing the cumulative errors due to hard pulses (i.e., rectangular pulses) employed with DD sequences.

Fluctuations can provide important additional information in sensing, for example, in gas recognition. Low-frequency noise due to adsorbent molecules and atoms on graphene has been demonstrated to yield distinct $1/f$ spectra (Rumyantsev et al., 2012). In combination with supervised-learning algorithms, based on statistical learning theory, fluctuation-enhanced gas recognition has already been investigated (Lentka et al., 2015). Such an approach may provide a significant boost in gas recognition resolution for e-nose applications (Chen et al., 2022).

For future superconducting quantum technology, clean materials are essential as they increase coherence time, which improves qubit operation, and along with it, increases the sensitivity of all schemes for quantum sensing. One of the central issues in this quest for better superconducting junctions and conductors is to understand the microscopic origin of $1/f$ noise on interfaces, surfaces, and tunneling barrier dielectrics. This will call for the systematic development of materials growth, cleaning, and fabrication techniques, as well as systematic benchmarking of the realized quantum components.

EDITOR-IN-CHIEF BIOGRAPHY

Tapash Chakraborty is a retired professor of physics from the University of Manitoba, Canada, where he was also the Canada Research Chair in Nanoscale Physics (2003–17). His research focus has been on many-body theories of various quantum materials, such as nuclear matter, helium liquids, and electron-hole liquids, that he studied under the tutelage of late Professor Manfred Ristig, at the University of Köln (1979–81). Just a year after the discovery of the fractional quantum Hall effect, he (working with his coworkers) demonstrated that electron–electron interactions could actually lead to quantum Hall states with nontrivial spin configurations, and that the low-lying excitations could be described as “spin-reversed quasiparticles.” This prediction motivated much experimental work from laboratories around the world, as a result of which the concept of spin-reversed quasi-particles was established.

Similarly, his work on the quantum Hall states in double layer systems has received much attention from the community. Furthermore, Dr. Chakraborty (working with Dr. P. Maksym and others) made pioneering contributions to the many-electron theory of quantum dots. Dr. Chakraborty has also contributed to the theory of electronic properties of various nanoscale systems, such as spin-orbit coupled quantum dots, quantum rings, and single- and double-layer graphene (primarily with Dr. V. Apalkov). He has authored many books and reviews: the book with Dr. Pietiläinen on the quantum Hall effect and the single-authored book on quantum dots have become standard references in their respective fields.

INTRODUCTION

Electrons in orbits contained by the quantum,
And atoms conjoined by the dipolar force,
Gravity balanced by pressure
And flap of a wing.
Here, I remember the angles and curves,
Calculus, I learned it all –
Each bird bit and moon fracture
Fixed by the symmetries,
Airborne and airless, aloft.

– Alan Lightman: *Song of Two Worlds*

Condensed matter physics (CMP) is the largest discipline in physics, involving a wide variety of interesting concepts and challenges. To quote [Leggett \(1992\)](#), CMP embraces topics “as diverse as traditional solid-state physics, neutron stars and the physics of biological matter.” He further added that, by a liberal definition “just about all of physics outside atomic, nuclear and particle physics and cosmology” fall in this vast enterprise¹. One of the primary goals of CMP is to explore the fundamental properties of matter—solids, liquids or gasses—comprising a large number of *interacting* constituent particles ([Laughlin and Pines, 2000](#)). The quantum-mechanical nature of these many-body systems makes condensed-matter highly nontrivial, sometimes counterintuitive and even astonishing. Superconductivity and the fractional quantum Hall effect (FQHE) naturally fall within that category. In fact, for the past four decades, the quantum Hall effects (QHEs) have been the epitome of elegant CMP ([von Klitzing et al., 2020](#)). Our fundamental system of units has been redefined following the discovery of the QHE when the “von Klitzing constant” $R_K = 25,812.8074593045 \, \Omega$ came into being ([von Klitzing, 2019](#); [Nawrocki, 2019](#)). Observation of the QHE in graphene² was crucial in determining the Dirac nature of charge carriers there (see for example, [Jiang et al., 2007](#)).

Another effect that outwardly resembles the QHE but is conceptually quite different is the FQHE, which is a quintessential manifestation of electron correlations governed by the Coulomb interaction ([Störmer, 1992](#); [Eisenstein and Stormer, 1990](#)). To explain this fascinating effect, [Laughlin \(1983\)](#) introduced his eponymous wave function that not only provided the foundation for understanding the effect but also triggered a new wave of ideas with impact far beyond the realm of CMP³. Who would have imagined that a large collection of interacting electrons confined on a plane in a perpendicular magnetic field would result in elementary excitations (quasiholes and quasiparticles) ([Chakraborty and Pietiläinen, 1988, 1995](#); [Halperin, 1983](#); [Clark and Maksym, 1989](#)) carrying fractional electron charge and obeying the exotic exchange statistics of anyons ([Halperin, 1984](#); [Arovas et al., 1984](#))? These quasiparticles and quasiholes of the Laughlin state still remain an enigma ([Laughlin, 1984](#); [Chakraborty, 1985](#); [Morf and Halperin, 1986](#)). Fractional statistics is a truly path-breaking concept in CMP that was introduced by [Leinaas and Myrheim \(1977\)](#), and has been recently confirmed experimentally ([Bartolomei et al., 2020](#); [Nakamura et al., 2020](#)).

Much of the history of CMP can be viewed as a series of paradigm shifts⁴. The field evolved rapidly through frequent ground-breaking discoveries that challenged existing paradigms and opened up new applications, and this evolution is expected to continue ([Leggett, 2018](#); [Cohen, 2008](#)). For example, our current understanding of

¹Interestingly, some similarities do exist between the mathematical frameworks that describe low-temperature CMP and early-universe cosmology. See [Kibble and Srivastava \(2013\)](#).

²An isolated single layer of graphite consisting of carbon atoms bonded together in a hexagonal structure. See, e.g., [Abergel et al. \(2010\)](#).

³For example, an important aspect of Laughlin's theory is its seamless concinnity of classical plasma physics and the planar electron gas that has inspired others to use a similar approach to quark-gluon plasma ([Lu, 2022](#)).

⁴A detailed exposition of the meaning and examples of “paradigm shifts” (Kuhn-type) can be found in [Leggett \(2018\)](#).

the FQHE required deep mathematical analysis and a wide range of experimental exploration, which revealed a treasure trove of unique phenomena that are yet to be fully understood or explained. Other studies of electron correlations in low spatial dimensions have ushered in many groundbreaking notions, such as Pfaffian states, Majorana fermions in condensed matter, Chern insulators, and topological quantum materials that promise a fault tolerant means to perform quantum computation. The presence of incompressible FQHE states in monolayer graphene (Apalkov and Chakraborty, 2006), bilayer graphene (Apalkov and Chakraborty, 2010, 2011), and double-layer graphene (Liu et al., 2019) has demonstrated the robustness of the effect, and provides invaluable insight into the nature of this effect.

The dynamics of an electron in a periodic potential subjected to a perpendicular magnetic field has been an intriguing problem for more than half a century (Obermair and Wannier, 1976; Osadchy and Avron, 2001)⁵. Within the nearest neighbor tight-binding description of the periodic potential the electron energy spectrum is described by the Harper equation (Harper, 1955). Numerical solution of this equation (Hofstadter, 1976) has revealed that the applied field splits the Bloch bands into subbands and gaps. As the field is varied, the splitting of band continues indefinitely, leading to bands within bands within bands. When plotted as a function of the magnetic flux per lattice cell, the energy spectrum depicts a *fractal* pattern (a self-similar pattern that repeats at every scale) and is known in the literature as Hofstadter's butterfly because of the resemblance of the pattern to butterflies⁶. Observation of the butterfly spectra in real systems is an arduous task. For example, in ordinary crystalline lattices, the required magnetic field to see the butterflies exceeds 1000 Tesla, which is far beyond the reach of present-day technology. Graphene seems to be the ideal system in the quest of those fractal butterflies (Weiss, 2013). It is interesting to note that a mathematical solution of the Harper equation, in contrast to the numerical solution mentioned above, remained a challenging problem (the so-called Ten Martini Problem) for mathematicians until it was solved (Avila and Jitomirskaya, 2006) in 2006.

Magnetism has been known to mankind since ancient times, and it remains a major topic in CMP. The road to understanding magnetism has been long and tortuous. At various times in history, magnets were claimed to have the healing power to cure a myriad of ailments that included epilepsy, arthritis, gout, and baldness. Magnets were the prime ingredients for the "elixir of life" by Paracelsus (1493–1541). Then there was the healing process of "animal magnetism" proposed by Franz Anton Mesmer (1734–1815) (mesmerism)⁷, which was famously mocked in Mozart's *Così fan tutte* (Stephoe, 1986). Our current understanding of magnetism is deeply rooted in quantum mechanics as Van Vleck explained (Van Vleck, 1978): "Quantum mechanics is the key to understand magnetism. When one enters the first room with this key there are unexpected rooms beyond, but it is always the master key that unlocks each door." For centuries, the magnetism of certain rocks and metallic iron was only used for the practical purposes of direction finding, particularly navigation with a compass. Motors, generators, and electrical distribution networks appeared only in the 19th century after the discovery of the deep connection between electricity and magnetism. Magnetic order is a collective phenomenon akin to superconductivity and superfluidity that involves a very large number of particles. The rich variety of magnetically ordered states in solids, not only ferromagnetism but also antiferromagnetism, ferrimagnetism, and a range of noncollinear structures, was confirmed only in the middle of the 20th century, with the availability of neutron beams in research reactors. A range of new magnetic materials are taking their place as active layers in thin film sensors and memory devices (Baltz et al., 2018). Besides information storage (Blundell, 2001), important technical applications include magnetic resonance imaging (MRI) and the use of magnetic nanoparticles in medicine.

Many outstanding discoveries in magnetism and magnetic materials have resulted in rapid advances in information storage technology. Over the last two decades spintronics has emerged as an important field of research both from the point of view of fundamental science and advanced technological applications (Yamaguchi et al., 2021; Pinarbasi and Kent, 2022). The giant magnetoresistance (GMR) effect, the spin Hall effect, and the spin galvanic effects are typical examples of developments in the field. Spintronics aims at understanding how the spin degree of freedom of the electrical carriers can be controlled in order to obtain devices with new functionalities and better performance. This endeavor often combines concepts from different aspects of condensed matter systems, giving the topic a fascinating interdisciplinary flavor. Spintronic phenomena are now being studied in an impressive range of different materials ranging from metals to half-metals to semiconductors, graphene and other two-dimensional systems such as transition metal dichalcogenides.

⁵For a recent review on butterflies in graphene, see for example Chakraborty and Apalkov (2015).

⁶However, as one of the authors of this Encyclopedia has (somewhat humorously) pointed out, this butterfly has Lebesgue measure zero, that is, it cannot fly!.

⁷A wonderful account of the use of magnetism in medicine since ancient times can be found in Mourino (1991).

The GMR effect and the related tunnel magnetoresistance effect (TMR) found their first commercial use in magnetic field sensors for hard-disk read-heads, before broadening their field of application to include magnetic sensors for the automobile industry, solid-state compasses, biosensors, and nonvolatile magnetic memory (Hartmann, 2000). The ability to manipulate the magnetic state of ferromagnetic structures led to initial developments in spintronics, where the spin direction was controlled by externally applied magnetic fields. However, the push for downscaling and faster timescales has prompted research advances in the past decade where the manipulation of magnetic configurations is achieved by local electric currents (the spin torque effect) (Brataas et al., 2012; Locatelli et al., 2014). In recent years, various novel concepts, such as chiral spintronics, skyrmionic spin textures, and magnetic domain walls in spintronics, have been actively pursued. The rate of progress in spintronics is truly astounding (Editorial, 2022).

In the past century, superconductivity has raised many theoretical challenges and triggered numerous technical developments. Discovered in mercury in 1911, this unique phenomenon occurs when the electrical resistance of many metals and alloys drops to zero when cooled below about 4 K, the temperature of liquid helium. More significantly, the material expels magnetic flux and becomes perfectly diamagnetic. Superconductivity has been adopted or evaluated for a wide range of technical applications (Rogalla and Kes, 2012). These include electric power generation, electric power transmission, high-speed maglev transportation, and ultra-strong magnetic field generation in high-resolution MRI and other nuclear magnetic resonance (NMR) systems. Interestingly, it took almost 50 years after the original discovery for the phenomena to be explained by the BCS theory (Tinkham, 2004) of reciprocal-space electron pairing, via the electron–phonon interaction. This electron–phonon mediated superconductivity became known as “conventional superconductivity” after the discovery of “high-temperature superconductivity” (Müller and Bednorz, 1987) at liquid nitrogen temperatures in tetragonal copper oxides in 1986. This threw open a new challenge to explain the properties of strongly correlated *anisotropic* electronic systems. Further new classes of superconductors that remain to be properly understood include the iron-based pnictides discovered in 2008 (Hosono et al., 2018). Recently, a two-dimensional superlattice made from a twisted bilayer of “magic angle” graphene was found to exhibit unconventional superconductivity (Cao et al., 2018), driven by electron–electron interactions.

The phenomenon of spontaneous symmetry breaking (SSB) is ubiquitous in physics, and plays a fundamental role in CMP, particle physics, and even in cosmology. A classic illustration of SSB being Heisenberg’s 1928 paper on ferromagnetism (Heisenberg, 1928). It is responsible for various collective modes, such as the famous Nambu-Goldstone (NG) and Higgs modes. Named by Baker and Glashow (Baker and Glashow, 1962), SSB corresponds to the case where the ground or lowest-energy state does not have the symmetry of the underlying dynamics. Instead, multiple degenerate ground states are available and the symmetry breaking is *spontaneous* because it is not clear, a priori, which one of those ground states will be chosen. In this well-trodden territory a simple analogy of this abstruse concept given by A. Salam is illuminating (CERN, 1977): “Imagine a banquet where guests sit at round tables. A bird’s eye view of the scene presents total symmetry, with serviettes alternating with people around each table. A person could equally well take a serviette from his right or from his left. The symmetry is spontaneously broken when one guest decides to pick up from his left and everyone else follows suit.” Over the years, development of the concept of SSB has taken a circuitous route (Gaudenzi, 2022): “from the land of particle physics to the physics of many bodies (solids and nuclei), from there to the province of superconductivity, and from the latter back to particle physics” SSB’s significance extends beyond the physics of the Higgs boson to the study of low-energy phenomena such as superconductivity, superfluidity, magnetism, and others. Historically, the particle physics community has been guided by this exploration in their quest to understand and discover particles like the Higgs boson. More to the point, when a continuous symmetry is spontaneously broken, a gapless mode, the NG mode, appears which governs the low-energy behavior of the system. As an example, in a solid, the acoustic phonon is the NG mode associated with translational symmetry breaking and determines the behavior of the specific heat at low temperature (the Debye T^3 law). Recently, signatures of Higgs and Goldstone modes have been proposed to exist in a perovskite oxide (Marthinsen et al., 2018), in other crystalline structures (Vallone, 2019), and also in various other quantum systems (Léonard et al., 2017). On a lighter note, it is the symmetry breaking that is claimed to have prevented the fabled donkey (Weintraub, 2012) in the parable by Jean Buridan (1300–50) from dying of starvation (Fubini, 1974).

Common to the theoretical descriptions of these phenomena across CMP and high-energy physics is Quantum field theory (QFT). QFT was originally developed to describe the fundamental processes in high-energy physics, but has now become a valuable tool to address problems across physics, in particular, in CMP (Fradkin, 2013; see also, Mustafa, 2023), statistical physics, modern quantum chemistry, and even in

pure mathematics (Folland, 2008). Advances in our understanding of strongly correlated electron systems in CMP such as high-temperature superconductivity and the FQHE have been aided by the QFT. It has facilitated the treatment of spontaneous symmetry broken states, such as superfluids. Interestingly, many of the conceptual developments in CMP have, in return, had a reciprocal impact in QFT. A spectacular example being Nambu's work in dynamical symmetry breaking (Weinberg, 1986; Nambu, 2009) in particle physics, based on the BCS theory of superconductivity.

A glass is a noncrystalline solid obtained by quenching a liquid. It has a liquid-like structure, but a transition from liquid to solid behavior occurs on cooling. It may have one of a continuum of possible ground states that exhibit frozen-in liquid-like disorder. The term “spin glass” was coined by B.R. Coles (Mydosh, 1993) in 1970 for a diluted magnetic material with frozen-in paramagnetic-like spin disorder where the magnetic moments interact with randomly varying positive or negative exchange interactions leading to a multitude of possible ground states with different, random orientations of the spins. As in a normal glass, the energy barriers between the continuum of metastable states prevent it from ever reaching equilibrium. This phase of condensed matter has been an important and productive area of research. Spin-glass models are conceptually simple, but embody sophisticated physics. These models have become a paradigm for the solution of complex optimization problems (Mézard, 2022): much like the undulating flight patterns of starlings around the skies over Rome (Parisi, 2023). After cooling from the paramagnetic phase, the spin glass remains out of equilibrium, and it slowly evolves. This aging phenomenon corresponds to the growth of a “spin-glass order” parameter, whose correlation length can be measured (Joh et al., 1999). A cooling temperature step during aging causes a partial “rejuvenation,” while the “memory” of previous aging is stored and can be retrieved (Refregier et al., 1987; Bouchaud et al., 2001). Many glassy materials present aging, and rejuvenation and memory effects can be found in other cases, but they are usually less pronounced. Numerical simulations of these phenomena are under active investigation using custom-built computers (Baity-Jesi et al., 2023; Vincent, 2023). A general understanding of glassy systems, to which spin glasses bring some special insight, is being pursued. It was realized decades ago that the physics of spin glasses has deep connections with the behavior of complex biological systems. In fact, spin-glass type states in neural network models offer interesting insights into states of high and low brain activity, as observed in mammals (Recio and Torres, 2016). These analogies are potentially useful for applications in fields such as robotics and artificial intelligence (AI) (Andriuschenko et al., 2022).

One of the most spectacular phenomena in CMP, discovered in the last century, was Bose-Einstein condensation (BEC). This macroscopic quantum phenomenon had its genesis in the work of Satyendra Nath Bose (Bose, 1924; Blanpied, 1972; Tomczyk, 2022) (whose name is forever associated with bosons), and has fascinated physicists for decades, ever since the first observation of this exotic state of matter in an ultracold gas of rubidium atoms (Georgescu, 2020). Among the advances made in this field, we highlight only a few: simulation of correlated electron states, such as the FQHE state and a bosonic analog of the Laughlin state, and the famous BEC-BCS crossover from a BEC to a BCS superfluid of weakly bound Cooper pairs, as the interparticle interaction strength is varied. Noteworthy is the recent measurement of the dynamic structure factor in an ultracold Fermi gas of lithium-6 atoms in the “unitary” limit, where a linear phonon mode for low momentum transfer can be clearly discerned (Biss et al., 2022). Perhaps such a method might one day shed light on the Laughlin quasiparticle gap and the collective modes that are still largely unresolved (Chakraborty and Pietiläinen, 1988, 1995; Halperin, 1983; Clark and Maksym, 1989).

Liquid helium, ^4He , and the less common isotope ^3He are unique quantum systems (Volovik, 2009). They remain liquid even at absolute zero temperature, a direct manifestation of Heisenberg's uncertainty principle and zero-point energy. The light mass of helium atoms and their weak interatomic attraction leads to a substantial zero-point kinetic energy and the system remains in the liquid state at ambient pressure. Solidification occurs when a pressure of about 25 MPa is applied. The different quantum statistics of the two helium isotopes (^4He is a boson while ^3He is a fermion) are responsible for the different physical characteristics of the two systems. Microscopic approaches to understand the ground state and low-energy excitations of the liquid state have occupied researchers for many decades (see for example, Ristig and Clark, 1976; Lam et al., 1977). These highly correlated quantum fluids have been established as systems where the efficacies of different many-body theories can be tested (Kallio and Smith, 1977; Lantto et al., 1977). These systems have been described as Ariadne's thread in this Encyclopedia, where the strongly interacting constituent particles are treated by a variety of ingenious theoretical and experimental approaches. Interestingly, liquid helium has been proposed to be a medium to design multiexcitation detectors to probe *dark matter* (Schutz and Zurek, 2016) in the keV mass limit. Although this looks far afield from CMP, the interface between CMP and high-energy particle physics could inspire new horizons in CMP, as discussed earlier.

CMP also has an enormous impact on our daily lives with unceasing technological innovation stemming directly from the advances in CMP research. It is also closely associated with the progress of our understanding of materials science and mechanical, chemical, and electrical engineering that deals with properties of novel materials and devices. As some authors have very aptly pointed out (Chaikin and Lubensky, 1995): The use and understanding of matter in its condensed (liquid or solid) state have gone hand in hand with the advances of civilization and technology since the first use of primitive tools. So important has the control of condensed matter been to man that prehistoric ages—the Stone Age, the Bronze Age, the Iron Age—are named after the material dominating the technology of the time. In fact, modern civilization is entirely dependent on our deep understanding and practical use of materials, old and new: Steel, glass, and concrete have shaped our modern living with comfort, health, longevity, and material wealth. All around us, from a tiny paper clip to giant skyscrapers, from jet planes to modern medicines, and the ubiquitous plastics that are integrated into nearly all aspects of human life, are testaments to our control over the myriad behavior of materials (Miodownik, 2014). Today, a large number of materials are designed by using principles of quantum mechanics (Freeman, 2002).

The Silicon chip that launched the information age is a great example of the effect of CMP on our daily lives. The scaling of transistors down to the nanometer range has enabled them to be embedded in greater numbers in the all-pervasive electronic devices that have transformed every facet of life all around the world. The transition from room-size to pocket-size computers with ever increasing computational power and memory, that occurred in only a few decades, epitomizes the unrelenting progress made in this direction. Advances in nanoscale research have opened the door to exploration of the natural world at the ultra-small scale (Chakraborty, 2022), with the potential to shape our future world.

Quantum dots (QDs), the quasi-zero-dimensional electron systems, are one of the most extensively studied nanostructures in the past three decades. They represent the ultimate reduction in dimensionality of a semiconductor device. Here the electrons are confined (either electrostatically or structurally) in all three directions and occupy spectrally sharp energy levels similar to those found in atoms (Chakraborty, 1999), hence the popular moniker *artificial atoms* (Maksym and Chakraborty, 1990). QDs and other similar nanostructures (Chakraborty, 2003) offer a rich variety of fundamental phenomena that result from manipulation of single electrons (single electronics) or single spins at the nanoscale. The study of interacting electrons in a QD requires large-scale numerical computations involving matrices of dimensions in the millions (“monster matrices”) (Chakraborty and Pietiläinen, 2005; Pietiläinen and Chakraborty, 2006). QDs are also thought to have vast potential for future technological applications. One prominent example being quantum cryptography where the QDs are used in single photon emitters (Nowak et al., 2014), and in single photon detectors (Shields et al., 2000). Quantum cryptography, in turn, forms the basis of the *quantum Internet* (Liao et al., 2018). Other applications include lasers, and spintronics in quantum computing, entertainment industry (Bourzac, 2013), and even in biology (Bruchez and Holz, 2007).

Research in recent years has increasingly revealed that quantum phenomena are also ubiquitous in the natural world (Ball, 2011). They govern how birds are able to navigate around the globe using Earth’s magnetic field or how plants use photosynthesis to harvest sunlight for conversion to chemical energy. All depend on subtle quantum effects that are now coming to light, thereby ushering the topic of quantum biology into CMP. Deoxyribonucleic acid (DNA), the molecule responsible for storage of genetic information in the cells of all living organism, is entrusted with the task of preserving, copying, and transmitting information that are necessary for living beings to grow and function. It is often referred to as the body’s hereditary material as DNA is replicated and transmitted from parents to their offspring. This “molecule of life” was discovered in 1869 by Friedrich Miescher in Tübingen, Germany, who called it “nuclein,” as it was isolated from the nucleus of white blood cells (Dahm, 2005; Thess et al., 2021). It took more than eighty years from that momentous event, to discover that DNA has a right-handed double-helix structure with appropriate base pairing (Watson and Crick, 1953; Klug, 2004). That discovery was so important that it has been compared with the discovery of the atomic nucleus in physics (Frank-Kamenetskii, 1997). Understanding the structure of the atom heralded quantum physics, while understanding of the structure of DNA brought forth the field of molecular biology.

DNA has several remarkable properties that make this molecule a prime candidate for nano-electronic materials (Chakraborty, 2007). These include molecular recognition and the ability to self-assemble via the complementarity of the base sequences on the two strands, which means that DNA can be integrated error-free in current semiconductor technology. DNA can also detect information about its own integrity that can trigger its eventual repair mechanism. All these properties are perfectly suitable for developing nanoscale electronics involving DNA

(Taniguchi and Kawai, 2006). Despite the promise of harnessing biology to realize integrated molecular electronics remains fascinating, much work remains to be done to make it a reality (Braun and Keren, 2004).

Protein molecules play a vital role in all living organisms. They are described as Nature's robots (Tanford and Reynolds, 2001) because for every imaginable task required in a living organism, and for every step of that task, there is a protein designed to carry it out. These proteins are even programmed to know when to turn on or off. Just as the twenty-six letters in the alphabet can spell out hundreds of thousands of words, there are twenty different naturally occurring amino acids that can be combined into many more different proteins than there are atoms in the known universe! Protein's biological function is determined by its unique and native three-dimensional structures that are characteristic of individual proteins (Gomes and Faísca, 2019; Echenique, 2007). The question of how proteins fold to their unique, compact, and highly organized functional states has remained an enduring challenge ("The protein-folding problem") (Chan and Dill, 1993; Dill and MacCallum, 2012; Wolynes and Eaton, 1999). Recently, there has been a tremendous development in this area of research. In November 2020, an AI program called AlphaFold, designed to tackle the problem of protein folding, predicted the three-dimensional structures of almost every protein known to science—about 200 millions in all (Jumper et al., 2021). AlphaFold uses a machine learning methodology to bring together information from preexisting knowledge of protein structures, and other geometric and physical constraints to predict protein structures. While this has been heralded a watershed moment in structural biology (Perrakis and Sixma, 2021), there are many key questions that AlphaFold cannot address yet. These include aspects of protein behavior that cannot be understood from a static structure, such as how proteins respond to their environment or how intrinsically disordered proteins actually are organized. Some authors (Nasser et al., 2021) have likened it to solving a crime story: while AlphaFold presents a snapshot in time, the question about how we get there remains unanswered. Biological systems have developed elaborate mechanisms to ensure that proteins fold correctly, or otherwise, they are detected and degraded before any serious harm can result to the host organism. However, protein misfolding does happen and that misfolding in the cell is linked to an array of diseases, including cancers, cardiovascular disease, type II diabetes, and numerous neurodegenerative diseases, such as Alzheimer's, Parkinson's, and Huntington's disease. NMR spectroscopy has been an important technique to study protein folding where valuable insights are gained into many aspects of the folding process (Jane Dyson and Wright, 1996).

In this Encyclopedia, we strive to present a taste of all the developments in CMP described above (and much more), written by experts in the field. We are keenly aware that many important and interesting topics are not covered here. However, that is not for want of trying. As some authors had rightly pointed out (Hoddeson, 1992): The field is huge and varied and lacks the unifying features beloved of historians, neither a single hypothesis or set of basic equations underpin the field, as in quantum mechanics or relativity theory, nor a single spectacular and fundamental discovery such as uranium fission for nuclear technology or the structure of DNA for molecular biology. CMP owes what unity it has simply to a common concern with solid and liquid materials. This encompasses such a large range of theories and methods that the field resembles a confederation of interest groups rather than a single entity. Clearly, the task of collecting everything in one place is a monumental endeavor, but we do hope that our compilation of a large number of chapters in this five-volume work, covering a broad range of in-depth descriptions of varied phenomena in CMP will be a treasured source of facts and ideas for the community.

It is undeniably true that there would have been no Encyclopedia without the extraordinary contributions of the large number of authors whose valuable time and efforts brought this project to fruition. My sincere thanks to all of them. I also wish to extend my deep appreciation to the staff at Elsevier for their skillful handling of this huge project. The cover image was created by Hong-Yi Chen from National Taiwan Normal University. The image below was created by Elisabetta Collini, one of the authors. My deepest appreciation to them for taking the time to do this work. Finally, my sincere thanks to the Section editors, Vladimir Fomin, Ana Sanchez, Roberto Raimondi, Hideo Aoki, Rudolf Römer, and Robert Blick for the effort they all expended, that has contributed to the success of this venture. Special thanks go to Vladimir Fomin and Ana Sanchez for securing a large share of the chapters and for their enduring help in providing valuable advice and support to bring the project to fruition. Thanks are also due to many of my friends and colleagues, in particular, Michael Coey, Jürg Fröhlich, Sinéad Griffin, Peter Maksym, Eric Vincent, and Jakob Yngvason for their careful and critical reading of the introduction.

LIST OF CONTRIBUTORS FOR VOLUME 2

Joel W Ager III

Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; Materials Science and Engineering Department, University of California Berkeley, Berkeley, CA, United States

Hiroki Ago

Global Innovation Center (GIC), Kyushu University, Fukuoka, Japan; Interdisciplinary Graduate School of Engineering Science, Kyushu University, Fukuoka, Japan

Ada Altieri

Laboratoire Matière et Systèmes Complexes (MSC), Université Paris Cité CNRS, Paris, France

Marco Baity-Jesi

Eawag (ETH), Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland

KH Bennemann

Physics Department, FU-Berlin, Berlin, Germany

EH Brandt[†]

CA Downing

Department of Physics and Astronomy, University of Exeter, Exeter, United Kingdom

G Chiarotti

Physics Department, Università di Roma "Tor Vergata", Rome, Italy

Andrey V Chubukov

School of Physics and Astronomy and William I. Fine Theoretical Physics Institute, University of Minnesota, Minneapolis, MN, United States

JMD Coey

School of Physics, Trinity College, Dublin, Ireland

PF de Châtel

New Mexico State University, Las Cruces, NM, USA

Paola De Padova

Consiglio Nazionale delle Ricerche-ISM, Roma, Italy; Istituto Nazionale di Fisica Nucleare-Laboratori Nazionali di Frascati—INFN-LNF, Frascati, Italy

MC Diamantini

NiPS Laboratory, INFN and Department of Physics and Geology, University of Perugia, Perugia, Italy

Oleksandr V Dobrovolskiy

Faculty of Physics, Nanomagnetism and Magnonics, Superconductivity and Spintronics Laboratory, University of Vienna, Vienna, Austria

Shi Xue Dou

Institute of Energy Materials Science (IEMS), University of Shanghai For Science and Technology, Shanghai, China

Rembert A Duine

Institute for Theoretical Physics, Utrecht University, Utrecht, The Netherlands; Department of Applied Physics, Eindhoven University of Technology, Eindhoven, The Netherlands; Department of Physics, Center for Quantum Spintronics, Norwegian University of Science and Technology, Trondheim, Norway

Mikhail I Dyakonov

Laboratoire Charles Coulomb, Université Montpellier, Montpellier, France; Ioffe Physical-Technical Institute, Saint Petersburg, Russia

David Emin

Department of Physics and Astronomy, University of New Mexico, Albuquerque, NM, United States

Klaus Ensslin

Physics Department, ETH Zurich, Zürich, Switzerland

MI Faley

ER-C-1 (Physics of Nanoscale Systems) Forschungszentrum Jülich, Jülich, Germany

J Fernández-Rossier

International Iberian Nanotechnology Laboratory, Braga, Portugal

[†]Deceased. The present version has been redrafted by Grigori Mikitik, B. Verkin Institute for Low Temperature Physics and Engineering of the NAS of Ukraine.

Abstract

Magnetism is a science with more than two millennia of recorded history. The attraction of ferrous objects to a permanent magnet across a distance has been a source of curiosity since the iron age. Investigations of magnetic phenomena led to the invention of steel magnets—needles and horseshoes—and the compass that enabled the exploration of the planet. A host of discoveries following Oersted’s 1821 demonstration of the relation between electric current and magnetic field led to the electromagnetic revolution that by the end of the 19th century had resulting in global communications and electrification. The discovery of the electron, together with the emergence of quantum theory and relativity in the early 20th century established the modern theoretical understanding of magnetism. A panoply of hard and soft magnetic materials has been developed to underpin the modern magnetics industry and a marriage of magnetism and electronics in thin film devices has eased the birth of the information revolution. Aside from the revolutionary technological advances, magnetism played a key role in clarifying basic concepts in condensed matter physics throughout the 20th century.

Key points

- Magnetic attraction was first investigated more than 2000 years ago with pieces of naturally-magnetized rocks rich in magnetite, Fe_3O_4 .
- Compasses using floating or pivoted steel magnets appeared in the 12th century. They led to the great voyages of discovery and mapping of the planet.
- Gilbert identified the Earth as the source of the directional magnetic attraction in 1600, and pioneered the modern experimental method of scientific investigation.
- Oersted’s 1820 discovery that electric currents create magnetic fields triggered a series of advances that culminated in Maxwell’s theory of electricity, magnetism and light, and practical electromagnetic energy conversion that revolutionized energy distribution and communication by the end of the 19th century.
- Then, with the discovery of the electron, and the demonstration that magnetism is associated with angular momentum, it became possible in 1928 to use relativity and quantum mechanics to explain magnetism as a consequence of the orbital and intrinsic spin angular momenta of electrons.
- The key practical achievement of the 20th century was the mastery of hysteresis, and the achievement of a wide variety of metallic or insulating hard and soft magnetic materials. Important outcomes were analog and digital magnetic recording and high-frequency electromagnetic devices.

[☆]*Change History:* February 2023. JMD Coey and F Mazaleyrat updated the chapter. Figs. 5, 6, 7, 10, 12, 13 are new or updated. Much of the text is revised or rewritten.

- Development of technology to produce uniform magnetic films just a few nanometers thick in the 1960s opened the prospect of using the spin of the electron to be used as well as its charge in electronic devices. Semiconductor electronics and magnetic memory are parents of the information revolution.
- Modern theory of condensed matter in areas such as phase transitions and topology has benefitted from magnetic model systems.

Nomenclature

$\hbar$	Planck's constant, 1.055×10^{-34} Js
B	Magnetic induction (T)
c	Speed of light, 2.99792458×10^8 ms ⁻¹
e	Charge on an electron, 1.602×10^{-19} C
H	Magnetic field strength (Am ⁻¹)
J	Exchange integral (J)
M	Magnetization (Am ⁻¹)
m_e	Mass of an electron, 9.109×10^{-31} kg
n_W	Weiss molecular field coefficient
S	Spin vector
T_c	Curie temperature (K)
ϵ_0	Electric permittivity of free space, 8.854×10^{-12} C ² N ⁻¹ m ⁻²
μ_0	Magnetic permeability of free space, $4\pi \times 10^{-7}$ TA ⁻¹ m
μ_B	Bohr magneton, 9.274×10^{-24} JT ⁻¹

Early history

Feeble permanent magnets are widespread in Nature in the form of lodestones, pieces of rock that are mainly composed of the iron oxide mineral magnetite (Fe₃O₄). Outcrops can be magnetized by the huge currents in lightning strikes and such natural magnets were known and studied in ancient Greece, Egypt, China and Mesoamerica. Aristotle attributed early thoughts on the nature of magnetic attraction to Thales, who was born in Milet in Asia Minor in 624 BCE. He was an animist who credited the magnet with a soul on account of its ability to create movement. This strange idea was to persist in Europe until the 17th century. The magnet itself is thought to be named after Magnesia, a city in Asia Minor that was a source of lodestone. In the 5th century BCE, when Empedokles postulated the existence of four elements, Earth, Water, Air and Fire; magnetism was related to Air with special effluvia somehow passing through pores in magnetic material, a theory echoed much later by Descartes. The Roman poet Lucretius writing in the 1st century BCE mentions the ability of a magnet to induce magnetism in iron and the ability of two magnets to either attract or repel; repulsion had been missed earlier. However, the Greek approach of developing a philosophy into which natural observations were supposed to fit was not conducive to open-minded exploration of the natural world.

A more productive approach was followed in China (Needham, 1962), where magnetism was linked to geomancy. The art of adapting the residences of the living and the tombs of the dead to harmonize with local currents of the cosmic breath demanded a knowledge of its direction. A South-pointer consisting of a carved lodestone spoon free to rotate upon a polished baseplate (Fig. 1) was in use in the 1st century BCE, and may have been known hundreds of years earlier. An important discovery, attributed to Zheng Gongliang in 1064, was that iron could acquire a thermoremanent magnetization when rapidly cooled from red heat in the ambient magnetic field. A short step led to the suspended magnetic needle, which was described by Shen Kua around 1088 and seen to deviate, like the South-pointer, from a strictly North-South axis.

The compass made its appearance in Europe about a hundred years later, being referred to by Alexander Neckham in 1190. Floating compasses were also developed around this time. The compass (Fig. 2) was the enabling technology for the great voyages of discovery of the 15th century, leading the Ming admiral Zheng He to the coasts of East Africa in 1420, and Christopher Columbus, who rediscovered declination, to America in 1492. Columbus's landfall was on the continent of the Olmecs, who seem to have had a knowledge of magnetism in their massive stone carvings of human figures and sea turtles dating from the second millennium BCE. Not long after these heroic voyages, the land masses and oceans of our planet were mapped and explored. According to Francis Bacon, writing in *Novum Organum* in 1620, the magnetic compass was one of the three things, along with printing and gunpowder, that had "changed the whole face and state of things throughout the world". All were Chinese inventions. It was the first occasion when magnetism changed the world. Two more were to follow.

The first authentic magnetic experimentalist in Europe was the French crusader monk Petrus Peregrinus. His paper *Epistola de Magnete* recounts experiments with floating pieces of lodestone and carved lodestone sphere that he called 'terellae,' performed

during the 1269 siege of Lucera, a Muslim settlement in Southern Italy. He discovered the poles of a magnet, related magnetic attraction to the celestial sphere, and included a proposal for a magnetic perpetual motion device—which has become an obsession of charlatans up to the present day. However, credit for the inauguration of the experimental method in a recognizably modern form belongs to William Gilbert. Physician to the English queen Elizabeth I, Gilbert conducted a series of experiments on *terellae* and concluded that the Earth itself was a great magnet. Magnets aligned themselves not with the celestial sphere, but with the Earth's poles. He induced magnetism by cooling iron in the Earth's field and destroyed it by heating or hammering. Gilbert was at pains to

dispel the accretion of superstition that clung to the magnet, preferring to rely on his own experimental evidence. His investigations are described in his masterwork *De Magnete* published in 1600 (Gilbert, 1958), which is arguably the first modern scientific text.

From navigation to industry

Gilbert's theories held sway in the 17th century until the appearance of Edmond Halley's 1692 shell model of the Earth's magnetic structure, which greatly influenced compass technology and navigation. Magnetic research at the time was driven principally by naval interests. An early observation of a connection between electricity and magnetism was made in 1681, when a ship bound for Boston was struck by lightning. It was evident from the stars that "the compasses were changed; the North point was turn'd clear South"; with the compass so reversed, the ship sailed on to its destination.

The 18th century was marked by professionalization of the scientist or 'natural philosopher' as they were then called (Fara, 1966). Developments in magnetism were associated with improvements in navigation and the prestige of the great voyages of discovery. Accordingly, the natural philosopher with his mantle of theory was afforded social status, access to public funding and credibility beyond that extended to artisans on the one hand, and quacks such as the colorful Anton Mesmer with his theories of 'animal magnetism' or James Graham with his 'royal Patagonian magnetic bed' for nightly rent in a fashionable London townhouse on the other. Halley conducted magnetic surveys, producing charts of inclination and declination for seafarers (Fig. 3). The English entrepreneur Gowin Knight, representative of this new breed of natural philosopher, later improved the quality of magnetic materials and compasses for sale to the Navy, coupling scientific endeavor with commercial acumen.

A major technical breakthrough of the 18th century was the 1755 discovery by Johann Dietrich that the horseshoe was an ideal magnet shape. His invention, an ingenious practical solution to the problem of self-demagnetization in steel bar magnets, was enthusiastically promoted by his patron Daniel Bernouilli.

This period also saw rapid developments in the harnessing of electricity, from the 1660 invention of the Leyden jar, culminating in Volta's 1800 invention of the Voltaic cell. There were compelling analogies between electrostatics and magnetism and some cogent speculation relating magnetism and rotational motion such as that of Richard Kirwan (1797), but a formal link between electricity and magnetism was not established experimentally until 1820. During a public demonstration by the Danish scientist Hans Christian Oersted, a suspended compass needle was found to be deflected when an electric current was switched on in a copper wire. His report launched an experimental frenzy. François Arago (who briefly became President of France in 1848) immediately performed an experiment in Paris establishing that a current-carrying conductor behaved like a magnet. A week after Arago's report, André-Marie Ampère presented a paper to the French Academy suggesting that ferromagnetism in a body was caused by internal currents flowing perpendicular to the magnetic axis and, by analogy, that steel needles magnetized in a solenoid would show stronger magnetization. Together with Arago, he successfully demonstrated his theory in November 1820. Ten days later, the British scientist Humphrey Davy reported similar results. A practical horseshoe electromagnet was constructed by William Sturgeon in 1825, and five years later Joseph Henry in the USA built a powerful electromagnet with layers of closely-spaced copper windings; he discovered self-induction and built an electric relay and an electric bell.

In the ensuing ferment in Europe and North America, it is often difficult to attribute credit for any particular advance, distinguishing between who had the idea, who devised a convincing experimental demonstration, and who created the first practical, working machine. Scientists and engineers belonged to different communities, with different preoccupations.

19th century electromagnetic science was driven, however, by Michael Faraday. Working entirely by observation and experimentation, with no dependence on formal theory, he developed the concept of 'magnetic field'. Faraday initially classified materials as magnetic (substances which are attracted by the field, either strongly like iron, nickel and cobalt or weakly like oxygen) or diamagnetic (materials which were pushed away by the field). The distinction between ferromagnets and paramagnets came later. Working with an electromagnet, he discovered the phenomenon of 'electromagnetic induction'— that a flow of electricity can be induced by a changing magnetic field. He demonstrated electrical $\leftrightarrow$ mechanical energy conversion in a model motor and a dynamo with steel permanent magnets, which were used in most of the early demonstrations, but electromagnets proved indispensable for later, practical electromagnetic machines. His conviction that a magnetic field should have an influence on light led to his 1845 discovery of the magneto-optic Faraday effect— the rotation of the plane of polarization of light passing through a magnetic medium in a direction parallel to its magnetization. Fig. 4 illustrates a collection of magnets from the 18th, 19th and late 20th centuries, when permanent magnets finally became indispensable for many practical applications.

A classical theory emerged to account simultaneously for magnetism and its relationship with electricity. Around 1824 Siméon Denis Poisson developed a mathematical theory of magnetostatics. Letters from Ampère to Fresnel and Faraday found after his death show that by 1822 he had considered the possibility that the currents causing ferromagnetism were 'molecular' rather than macroscopic in form. Wilhelm Weber formally presented the idea that 'molecules' of iron were capable of movement around their centers, suggesting that they lay in different directions in unmagnetized material, but aligned in a common direction in the presence of an applied magnetic field. This was the beginning of an explanation of hysteresis, the central phenomenon of technical magnetism, demonstrated experimentally by James Ewing using a board with an array of small, pivoting magnets. He then built an ingenious instrument based on the bending of a ferromagnetic current-carrying wire in the gap of an electromagnet to measure B and H under AC and DC excitation, with which he discovered and measured hysteresis loops in 1889 (Fig. 5). Ewing's activities as a young professor at the University of Tokyo in the 1890s established the strong Japanese tradition of research on magnetic materials that continues to thrive to this day.

Fig. 3 A section of Halley's world chart of magnetic variation published in 1700.

James Clerk Maxwell, the Scottish theoretician, "resolved to read no mathematics on the subject till he had first read through Faraday's *'Experimental Researches in Electricity'*". Maxwell's unprecedented equations formally defined the relationship between electricity and magnetism and bridged the gap, between oscillating electric charge and magnetic field. His theory considered electromagnetic waves traveling through an all-pervading aether at speeds close to that of light, measured with 5% accuracy by Hyppolite Fizeau in 1849.—In 1888 Heinrich Hertz showed that Maxwell's electromagnetic waves were, in fact, identical with radio waves and light.

The subsequent technological developments of all these discoveries would have been impossible without a stable and powerful source of electric energy that batteries were unable to provide. Starting from Faraday's rotation, Arago's rotary magnetism and his own understanding of electrodynamics, Ampère and the young instrument maker Hypolyte Pixii demonstrated the principle of a

Fig. 5 James Ewing's automatic hysteresis loop tracer. The sample is in the form of two long steel bars contained within the two horizontal solenoids (Ewing, 1982).

DC generator in 1832. The first DC motor with a commutator came two years later (credit has been claimed for Moritz von Jacobi in Russia, Anyos Jedlic in Hungary and Thomas and Emily Davenport in Vermont), but the first industrial machine issued from Siemens brothers' workshop only in 1854. However, these energy converters needed very big steel magnets to work effectively. The English engineer Henry Wilde dared in 1864 to replace permanent magnets with a series of multi-turn electromagnets in a dynamo thereby reduced the mass while greatly improving the performance. A similar machine was built independently by Werner von Siemens shortly afterwards. A new design of DC generator came in 1859 from Antonio Pacinotti in Italy. His innovation, published only in 1865, was in the design of the rotor (Pacinotti's ring) that improved the efficiency. With further improvements, the design was launched commercially in 1870 by Zénobe Gramme in France. In addition to Pacinotti's ring, Gramme fed the electromagnet directly from the rotor (Fig. 6). Then with further modifications to reduce the mass and increase the efficiency, notably by Siemens, the design was stabilized. Surprisingly, the reversibility of the DC generator was observed by Hyppolite Fontaine only in 1873; he found that by applying a DC current to Gramme's machine he could make it spin.

The first electric streetlights were bright high-voltage DC arc discharge lamps with short-lived elements that replaced the gas lights of Paris in 1879, but they were deemed too dangerous for domestic use. In 1882, Thomas Edison built the first system of electric distribution for 59 customers in New York and developed a working light bulb operating at 110 V DC. However, the expansion of the electric power grid was only made possible by Nikola Tesla's AC system, which enabled efficient long-range distribution at high voltages with minimal electrical losses together with a safe local voltage achieved by means of step-down transformers. Based on Elihu Thomson's AC generator (1879), the transformer of Lucien Gaulard and John Gibbs (1881) and

Fig. 6 Zénobe Gramme's dynamo (1870).

Tesla's induction motor (1886), this system was taken on by the Westinghouse company, and it has remained almost unchanged up to the present day.

Siemens exhibited a miniature electric locomotive pulling a little train around a 300 m track to amuse visitors at a Berlin exhibition in 1879. His company installed the first electric trams in Berlin two years later and by 1900 they had an electric train capable of 200 kmh^{-1} . Horses and their droppings soon vanished from city streets.

One of the problems besetting the development of efficient magnetic material in the 19th century was the difficulty to measure magnetization and field precisely. Coulomb adapted the principle of the electrostatic torsion balance in 1784 to measure electric charge, but it could only work approximately with the inseparable 'poles' of permanent magnets; the magnetic moment couldn't be fitted into the existing system of units. By 1880, it was possible to estimate the permeability by AC voltage and current measurements. John Hopkinson, in 1885, observed the enhancement of permeability just before reaching the temperature at which ferromagnetism disappears. After the invention of the first ballistic galvanometer or fluxmeter (actually an electromechanical voltage integrator) by Arsène d'Arsonval around 1881, it became possible to measure time- or space-varying fields. It was by using this instrument that Pierre Curie could measure a magnetic field and its gradient. With the very sensitive torsion balance illustrated in Fig. 7 that could operate in large fields and at high temperature, he determined his law of paramagnetism, showing that ferromagnets behave like paramagnets above their magnetic transition temperature—known ever since as the Curie point.

The astonishing transformation of science and society that began in 1820 is known as the *electromagnetic revolution*. By the end of the century the revolution was heralding the electrification of the planet and changing forever human communications, transportation and conditions of life and leisure. This was the second time that magnetic technology changed the world.

Finally, the century closed with the all-important discovery of the electron, the elusive carrier of electricity. A new age was born.

For further information, the reader may refer to one-volume histories of magnetism (Kloss, 1994), and of electricity and magnetism (Meyer, 1972; Mottelay, 1975), and a short accounts of in magnetism textbooks (Matthis, 1965; Coey, 2010).

Units

By the middle of the 19th century, it was becoming urgent to devise a standard set of units for electrical and magnetic quantities. The burgeoning telegraph industry, for example, needed a standard of electrical resistance to control the quality of electrical cables. Separate electrostatic and electromagnetic cgs unit systems based on the gram, centimeter and second had come into existence. Maxwell and Jenkin proposed combining them in a coherent set of units in 1863. Their Gaussian cgs system was internationally adopted in 1881. Written according to this system, Maxwell's equations relating electric and magnetic fields contain factors of c , the velocity of light. Maxwell also introduced the idea of dimensional analysis, based on three basic quantities of mass, length and time. The magnetic field H and the induction B were measured in units of Oersted and Gauss, respectively in the cgs system, but there is no numerical distinction between them in free space.

Another basic unit, that of electric current, was adopted in the *Système International d'Unités* (SI) in 1948. The number of basic units and dimensions in any system is an arbitrary choice; SI uses the meter, kilogram, second and ampere. It has been adopted

Fig. 7 Pierre Curie's torsion balance used for quantitative measurements of magnetic susceptibility at high temperature in a horizontal magnetic field gradient (Curie, 1895).

worldwide for the teaching of science and engineering, employing the familiar electrical units of volt, ampere and ohm. Maxwell's equations written in terms of two electric and two magnetic fields contain no factors of c or 4π in the SI system. The magnetic field H , like the magnetization M , has units of Am^{-1} . The induction B is measured in tesla ($1 \text{ T} \equiv 1 \text{ kgs}^2 \text{ A}^{-2}$). Magnetic moments are measured in units of Am^2 , clearly indicating the origin of magnetism in electric currents, and the consequent absence of magnetic 'poles' as real physical entities. The velocity of light is defined as exactly $299,792,458 \text{ ms}^{-1}$. Two constants μ_0 and ϵ_0 , the permeability and permittivity of free space respectively, are related by $\mu_0 \epsilon_0 = c^{-2}$. μ_0 was defined to be $4\pi \cdot 10^{-7} \text{ kgs}^2 \text{ A}^{-2}$ until 20 May 2019, but with the new definition of the ampere and the retirement of the Pt—Ir standard kilogram, it is now defined as $1.25663706212(19) \times 10^{-6} \text{ kgs}^2 \text{ A}^{-1}$ which differs only in the tenth digit from $4\pi \cdot 10^{-7}$.

Gaussian cgs units remain in widespread use in magnetism in some parts of the world, despite the manifest practical advantages of SI.

Fundamental understanding

The discovery of the electron in the closing years of the 19th century was a giant step towards a fundamental understanding of magnetism. The elementary charged particle with mass $m_e = 9.109 \times 10^{-31} \text{ kg}$ and charge $e = -1.602 \times 10^{-19} \text{ C}$ had been named by the Irish scientist George Johnstone Stoney in 1891, several years before Jean Perrin identified negatively charged particles in a cathode ray tube and Joseph John Thompson measured their charge to mass ratio e/m_e by deflecting them in a magnetic field. George Francis Fitzgerald suggested in 1900 that magnetism might be due to rotation of these electrons. Electrons turned out to be the essential magnetic constituent of atoms and solids, as well as the carriers of electric current.

Based on measurements of the low-temperature saturation magnetization of iron and nickel, and the paramagnetic properties of transition metals salts, Weiss proposed in 1911 an experimental unit of atomic magnetism $\mu_W = 1.853 \times 10^{-24} \text{ JT}^{-1}$. Known as the Weiss magneton, it remained in use for about 30 years, notably by Blas Cabrera in Spain who used it to interpret very precise measurements of susceptibility above the Curie point. It was abandoned in favor of the Bohr magneton $\mu_B = e\hbar/2m_e = 9.274 \times 10^{-24} \text{ JT}^{-1}$, which involves the quantum of angular momentum $\hbar$ (Quédec, 1988). The Einstein-de Haas experiment established a relation between magnetization and angular momentum experimentally, in 1915. The intrinsic spin angular momentum of the electron was unknown at that time (Tomonaga, 1974).

Thirty years were to elapse before contradictions at the heart of early 20th century magnetism could be resolved. In these tumultuous years, classical physics and the lingering wisps of aether were blown away, and new principles of quantum mechanics and relativity were established. If, following Ampère, we believe that all magnetism is traceable to circulating electric currents, why does iron not melt? Its magnetization M is equivalent to a surface current of $1.76 \times 10^6 \text{ Am}^{-1}$, how could such a current be sustained indefinitely? Weiss had postulated in 1907 the existence of an internal ‘molecular field’ proportional to the magnetization, $H_i = n_W M$, to account for the abrupt disappearance of ferromagnetism at the Curie point T_C and paramagnetism at higher temperatures. He was at a loss, however, to explain why no trace of his enormous field—a thousand tesla ($n_W \approx 1000$)—was detectable in the vicinity of a piece of fully-magnetized ferromagnetic material, as predicted by the continuity of B in Maxwell’s equation. He concluded that the origin of this field must be electrostatic (Weiss and Foëx, 1926). In the unmagnetized state Weiss had accepted the existence of domains magnetized in different directions to give no resultant moment, but there are no domains in the saturated state. The ‘anomalous’ Zeeman splitting of spectral lines in a magnetic field was a mystery. Niels Bohr in 1911 and Hendrika van Leeuwen in 1919 had proved that at any finite temperature and in any magnetic or electric field, the net magnetization of any collection of classical electrons vanishes identically. Classical electron physics was incompatible with any kind of magnetism whatsoever!

By 1930, quantum mechanics and relativity had come to the rescue, and a new understanding of magnetism emerged in terms of the physics of Einstein, Bohr, Pauli, Dirac, Schrödinger and Heisenberg. The source of magnetism in condensed matter was identified with the *angular momentum* of elementary particles such as the electron. The perpetual currents in atoms were quantized in stationary states that did not decay, with angular momentum that was a multiple of Planck’s constant $\hbar = 1.055 \times 10^{-34} \text{ Js}$. Weiss’s ‘molecular field’ was not a magnetic field at all, but a manifestation of electrostatic Coulomb interactions constrained by Pauli’s exclusion principle, which forbade the occupancy of a quantum state by two electrons with the same spin. The intrinsic spin angular momentum of an electron was found by Samuel Goudsmit and George Uhlenbeck in 1925 to have the value $\frac{1}{2}\hbar$. The corresponding electronic magnetic moment, however, was one Bohr magneton, twice as large as anticipated for orbital angular momentum. The problem of the electron’s magnetism was finally resolved by Paul Dirac in 1928 when he succeeded in writing Erwin Schrödinger’s equation in a relativistically invariant form, obtaining the electron spin in terms of the 2×2 spinor matrices previously proposed by Wolfgang Pauli. Together with Werner Heisenberg, Dirac formulated the Hamiltonian $-2JS_i \cdot S_j$ to describe the coupling between the vector spins S_i and S_j of to many-electron atoms i and j . The value of the exchange integral J was directly proportional to Weiss’s molecular field coefficient n_W .

The theory was almost complete after the description of spin waves by Felix Bloch in 1930 as the elementary excitations of an array of atoms coupled by Heisenberg exchange interactions, and the band theory of ferromagnetic metals developed by Edmund Stoner and John Slater in the 1930s, which accounted for the non-integral spin moments found in Fe, Co and Ni, and their alloys.

The sixth Solvay conference, held in Brussels in October 1930, (Fig. 8) was devoted to magnetism (Marage and Wallenborn, 1995). It followed 4 years of brilliant discovery in theoretical physics, which set out the modern electronic theory of matter. Yet the

immediate effect on the practical development of magnetism was surprisingly slight. Dirac there made the perceptive remark “The underlying physical laws necessary for the mathematical theory of a large part of physics and the whole of chemistry are completely known, and the difficulty is only that the exact application of these laws leads to equations much too complicated to be soluble”.

Magnetic phenomenology and materials

A less fundamental theoretical approach was needed. Louis Néel, a student of Weiss, pursued a phenomenological approach to magnetism, oblivious to the triumphs of quantum mechanics. His extension of Weiss theory to two oppositely-aligned sublattices led to the idea of anti-ferromagnetism in 1932. This hidden magnetic order awaited the development of neutron scattering in the 1950s before it could be revealed directly. Néel later explained the ferrimagnetism of oxides such as magnetite (Fe_3O_4)—the main constituent of lodestone—in terms of two unequal, antiferromagnetically-coupled sublattices. The spinel structure of magnetite has an ‘A’ sublattice of iron sites in tetrahedral oxygen coordination, and twice as many sites in octahedral coordination forming a ‘B’ sublattice. The ‘B’ sites are occupied by a mixture of Fe^{2+} and Fe^{3+} , and the ‘A’ sites by oppositely-aligned Fe^{3+} . This yields a net spin moment of $4\mu_B$ per formula—a quantitative explanation of the magnetism of the archetypal magnet in terms of lattice geometry and atomic moments associated with electron spin.

An important family of spinel ferrites derived from magnetite was developed by Jacobus Snoek at the Philips Research Laboratory, beginning in the 30’s and more intensively following Néel’s theory of ferrimagnetism. The expansion of radio communications has been possible, thanks to Ni—Zn ferrites and power electronics for phone or car chargers; choppers and inverters for DC and AC motors and rectifiers could not have advanced without Mn—Zn ferrites. Mg ferrite was used for television tubes and the countless thousands of 2 mm ferrite rings threaded on a lattice of copper wires that served as non-volatile computer memories in the 1970s. Another family of ferrimagnetic iron oxides, the rare-earth iron garnets, included $\text{Y}_3\text{Fe}_5\text{O}_{12}$, the ideal material for low-loss microwave components. For some time, Co ferrite was used for hard magnets, but a decisive breakthrough was the discovery at Philips in 1953 of a family of hexagonal ferrite permanent magnets based on $\text{BaFe}_{12}\text{O}_{19}$, which were the first magnets to break the shape barrier. They were endowed with sufficient coercivity to be fabricated into any desired shape without self-demagnetization. Electromagnetic machine design was freed at last from the shackles of the horseshoe. As a result, a million tons of hard ferrite is being produced every year to make billions of small DC motors and actuators.

For many practical purposes, it is possible to ignore the atomic and electronic basis of magnetism, and simply regard the magnetization of a solid as a continuous vector. The hysteresis loop $M(H)$ (Fig. 9) is a record of the resultant of a metastable structure of domains and domain walls arising from the thermal and magnetic history of a particular sample. Evidence for discontinuous jumps in the Weiss domains as the magnetization was saturated was picked up with headphones by Heinrich Barkhausen in 1919, and in 1931 the domains were visualized in a microscope by Francis Bitter using a colloidal suspension of magnetite particles.

Bloch introduced the idea of a domain wall in 1932 as a region where the magnetization rotates continuously from one direction to another. The exchange energy cost, written in the continuum approximation as $A(\nabla M)^2$ where $A \propto J$, is balanced by the gain in magnetostatic energy $\frac{1}{2}\mu_0 H^2 dV$ associated with the magnetic field created by the ferromagnet throughout its own and the surrounding space, where V is volume. Another term, the anisotropy energy, is needed to restrict the wall width, which can arise from the sample shape, or intrinsically from spin-orbit coupling, a relativistic effect. The sum of these free energy terms, together with the Zeeman energy in an external field, is minimized to yield the domain structure. Based on these concepts, Lev Landau in 1935 explained the formation of domains such as closure domains in iron single-crystals. The complete theory of ‘micromagnetism’ was formulated by William Fuller Brown in 1940. However, describing the macroscopic magnetic properties from microscopic equations remains an formidable challenge. So far, hysteresis has been modelled using the approach proposed by the Hungarian engineer Ferenc Preisach, a student of Barkhausen, in 1935 (Vajda and Della Torre, 1995).

Fig. 9 The hysteresis loop of M against H for a typical permanent magnet. M_s is the saturation magnetization, M_r the remanent magnetization at zero applied field, and H_c the coercive field required to reduce the magnetization to zero.

Domain walls in solids tend to be pinned by local crystal imperfections or microstructures, leading to the metastable states represented on a hysteresis loop. The control of hysteresis was the main challenge for magnetic materials design in the 20th century, and the challenge was met more by metallurgical art than by recourse to fundamental physical theory. Back the 19th century, practical ferromagnetic magnetic materials were limited to soft low-carbon and hard high-carbon steels with additives such as Co, Cr or W. Progress with soft magnets was rapid after Robert Hadfield, working in Sheffield in 1900, discovered the improved mechanical behavior and higher resistivity of silicon steel. Mass production of Fe—Si sheets began in Germany the same year. A lower magnetization was offset by much lower AC losses, and improved efficiency of generators, motors and especially transformers after the development of textured grain-oriented silicon steels by Norman Goss in 1937.

A significant improvement of hard magnets beginning in 1932 was due to the Japanese metallurgist Tokushichi Mishima, who found that adding Al to Ni—Fe alloys improved their hard magnetic properties. Addition of Co with traces of other elements, and development of a series of complex heat treatments gave us the family of ‘Alnico’ alloys over the following 50 years. All have elongated nanoparticles of soft ferromagnetic Fe—Co in a paramagnetic Ni—Al matrix. The magnetic hardness and coercivity is due to the shape anisotropy of the separated nanoparticles.

The mastery of coercivity gained over the course of the 20th century (Fig. 10) was spectacular. Burgeoning applications of magnetism were the direct consequence. Microscopic quantum theory only began to contribute to this process in the 1970s after the advent of rare earth permanent magnets such as SmCo_5 and $\text{Nd}_2\text{Fe}_{14}\text{B}$ in particular, where an understanding of the quantum mechanics of intrinsic, magnetocrystalline anisotropy helped in the design of new permanent magnet materials.

A fertile approach to the problem of hysteresis was to focus on magnetization reversal in the simplest case of single-domain particles. Edmund Stoner and Peter Wohlfarth proposed an influential model for this in 1948. Néel had envisaged magnets made from elongated iron particles in 1942 and published some results in one the short notes he wrote for *Comptes Rendus* in 1947. Seeking to understand the remanent magnetism of baked clay, Néel proposed a model of thermally-driven ‘superparamagnetic’ fluctuations of the magnetization of micron-sized ferrimagnetic particles the following year. The fluctuation time depended exponentially on the ratio of the magnetization reversal energy barrier to the thermal energy. As a result, a component of magnetization became blocked on cooling in the Earth’s magnetic field. Application of this idea of thermoremanent magnetization to cooling igneous rocks delivered a direct and convincing argument for continental drift, as rocks cooling at different times experienced fields of different polarity (Fig. 11). This all led to the subfield of palaeomagnetism, and establishment of the theory of global plate tectonics, which had far-reaching consequences for Earth science (McElhinney, 1973).

Fig. 10 The development of coercivity in the 20th century.

Fig. 11 Sign of the thermoremanent magnetization measured across the floor of the Atlantic ocean. Random reversals of the Earth's field, which are dated from other igneous lava flows, follow a chronological pattern which determines the rate of continental drift (McElhinney, 1973). Courtesy of Cambridge University Press.

The Earth's magnetism had been a perennial topic of interest since the seminal work of Gilbert. Alexander von Humboldt, who became interested in 'magnetic storms' in the course of his travels in South America where he made numerous measurements of the Earth's field, organized a group of laboratories in Paris, Freiburg, Berlin and Kazan to make synchronous measurements of the field in the course of a single day in March 1829.

Remarkably, all of them revealed the same pattern of short-term fluctuations. Humboldt's embryonic *Magnetische Verein* was soon entrusted to Wilhelm Weber and Carl Friedrich Gauss in Göttingen, who expanded the collaboration to include dozens of magnetic observatories across Europe, Asia and North America, spanning the globe from Dublin to Alaska. They collated worldwide measurements made on a daily schedule of Göttingen time in an unprecedented international scientific collaboration aimed at understanding the behavior of the Earth's magnetic field. It lasted until 1841 and continued in another guise for a further decade. Gauss developed spherical harmonic analysis to reduce the data and concluded that the greater part of the field was of internal origin. The external component was associated with an 11-year cycle of sunspot activity by Edward Sabine, but no amount of data, however scrupulously acquired, was capable of predicting the variations of system that was essentially chaotic.

Modern developments

Magnetism since 1945 has been an area of rich and productive discovery, not least because of the enormous increase in numbers of scientists and engineers working in the field. Magnet ownership for citizens of the developed world has skyrocketed from one or two magnets in 1945 to a few hundred 75 years later, or something of order a trillion if we count the individual magnetic bits on a hard disc in a personal computer! Magnetic recording dates from the final years of the 19th century, when the Danish engineer Valdemar Poulsen recorded his voice on steel wire (Daniel et al., 1999). It developed into analog recording on tape covered with ferrimagnetic microparticles in Germany in the 1930s but in the modern era, digital recording has come to overshadow all else. Hard discs, introduced by IBM in 1957 offer large amounts of nonvolatile computer memory. Initially using inductive read-write heads and particulate media, they developed to provide the bulk of the mass storage in data centers, where all the readily-accessible information of the internet is stored. Much non-volatile personal data is now recorded in semiconductor flash memory, but archival back-up storage of mountains of digital data generated daily uses magnetic tape. Magnets and semiconductors were the mainstays of the first decades of the information revolution—semiconductors to process the data and magnets to store it. The success of magnetic recording lay in its ability to keep pace with the relentless exponential doubling of the areal density of transistors on silicon chips every one or two years. This is due to the scale-invariance of the dipole field of a pattern of permanent magnetism, and the ability of spin electronics to develop magnetic field sensors based on thin film stacks that can operate on ever-smaller length scales. Magnetic recording is a pillar of the information society.

Modern achievements can be classified as those contributing to a basic understanding of condensed matter, those associated with new experimental probes, and those leading to new materials, preparation methods and industrial technologies.

Theory

From a fundamental viewpoint, magnetism has been a fertile field for cultivating condensed-matter theory. After Weiss's original mean-field theory, magnetism has inspired more sophisticated theories of phase transitions, and provided the data to support

them. A milestone was Onsager's 1944 solution of the two-dimensional Ising model, where spins are regarded as scalars which take values ± 1 . The behavior of more complex and realistic systems such as the three-dimensional Heisenberg model were solved numerically using the renormalization group technique in the 1970s. The ability to tailor magnetic model systems having an effective spatial dimension of 1 or 2 with structures of isolated chains or planes of magnetic ions and an effective spin dimension similarly limited by anisotropy to 1, 2 or 3 in the Ising, xy or Heisenberg models, laid the foundation of the modern theory of phase transitions.

Coulomb correlations among the electrons in a metal, and their coupling to the crystal lattice, generate a wealth of ground states and unexpected phenomena in solids. Experimental studies of dilute magnetic alloys such as AuFe or CuMn raised two questions that preoccupied theorists in the last decades of the 20th century. One was whether a single atomic impurity in a nonmagnetic metal can retain its magnetic moment. The question focused attention on the relation between magnetism and electronic transport in metals, a nexus that has been immensely productive. The other concerned the nature of the transition to the 'spin glass' state when the magnetic moments of the impurities freeze in random directions at sufficiently low temperatures. The single impurity problem was related to a shallow resistivity minimum at low temperature where the atom appears to lose its magnetic moment. The effect was explained by Jun Kondo using perturbation theory for spin-flip scattering, where the impurity enters a singlet state due to Coulomb interaction with the conduction electrons. The Kondo problem was eventually solved exactly in 1983 by Natan Andrei. In spin glasses, multiple dilute impurities interact with each other via indirect 'RKKY' exchange through spin polarization of the conduction electrons, which produces a symmetric Gaussian distribution of positive and negative exchange interactions J . Spin glasses show a frequency-dependent peak of the magnetic susceptibility at the spin freezing temperature T_f , which it is thought would be a thermodynamic phase transition for Heisenberg spins in four spatial dimensions. The wider problem of spin freezing in amorphous solids resulting from topologically-frustrated antiferromagnetic interactions in odd-membered rings or random single-ion anisotropy, especially for rare-earth atoms, was investigated in the context of amorphous magnetism in the 1970s, as discussed further in the following section on Materials.

Theoretical studies of the ground states of chains, ladders, triangular lattices and the two-dimensional electron gas catalyzed a wider understanding of the role of topology in condensed matter, where magnetism has provided model systems that help to clarify the concepts. Topological properties of matter are invariant under small changes of external variables—pressure, temperature, or magnetic field—unlike the usual linear response. An early example of topological quantum matter was the one dimensional, $S = 1$ antiferromagnetic chain that Duncan Haldane discovered in 1981 exhibited a spin gap and behaved as a quantum spin liquid. At about the same time, Klaus von Klitzig at the Grenoble High Magnetic Field Laboratory discovered that the Hall effect in the two-dimensional electron gas of a silicon MOSFET exhibited a series of steps in applied field, where the Hall conductance was a precise integral multiple of e^2/h , to within one part in a billion. This provided a new standard of resistance $h/e^2 = 25.81280745 \text{ k}\Omega$. A corresponding quantum anomalous Hall effect was observed in magnetic materials in the absence of an applied field. The anomalous Hall effect, itself a puzzle for over a 100 years after its discovery by Edwin Hall in 1879, was interpreted as an intrinsic feature of a ferromagnetic metal related to the topology of the band structure, characterized by its Berry curvature.

Numerical simulations

With the arrival of cheap, powerful computers in the 1990s, numerical simulations of the electronic structure and properties of ideal crystals based on spin-dependent density-functional theory became widespread. They opened the prospect of discovering potentially-interesting new magnetic materials without the bother of entering a laboratory. Simulations were successfully applied to calculate the magnetic ground state properties of correlated electrons in metallic systems, and obtain magnetization, anisotropy and Curie temperature. Phase stability may depend on stoichiometry, disorder or a variety of crystallographic defects, and a single phase may be unstable with respect to disproportionation into a lower-energy combination of two or more phases. While no new magnetic materials have yet been discovered that are worthy to join the handful that can be profitably commercialized, the method provides insight into trends in the electronic structure and properties of large numbers of ideal compounds but fall short of handling the complexity of real materials. Numerical simulations began to accompany experimental reports on properties of magnetic materials. Machine learning from large databases of known phases can improve the accuracy of predicted magnetic properties such as Curie temperature.

On a different scale, simulations based on the Landau-Lifschitz-Gilbert equation are appropriate for simulating the short-term dynamics and micromagnetism of microscopic systems. The mesoscopic scale is computationally the most demanding.

Experimental methods

Force magnetometers remained in use for most of the 20th century for static measurements of magnetization and susceptibility. DC magnetometers based on the ballistic galvanometer were replaced by electronic integrators based on John Ragazzini's valve-based operational amplifiers (1947) and their solid-state successors (1968), and then usually by digital integration. The vibrating sample magnetometer (VSM), a laboratory workhorse, was invented by Simon Foner in 1959 to measure the voltage induced in a quadrupole pickup coil by the oscillatory movement of a magnetized sample using a phase-sensitive lock-in detector, thereby converting a one-shot measurement to the continuous detection of a steady voltage. The principle is similar to that of the electric guitar microphone invented by Adolf Rickenbacker in 1931. Due to its versatility and sensitivity of order 10^{-8} Am^2 or $10^{15} \mu_B$, the VSM became the standard laboratory method for measuring magnetic moment, either equipped with an electromagnet or a

superconducting coil. A trend in laboratory experiments has been to generate and process ever-growing quantities of data, thanks due to the ability of computers to accumulate and store digital information on ever-shorter timescales. The precision and detail of the measurement is thereby enhanced.

The discovery of magnetic resonance, the sharp absorption of microwave or radio-frequency radiation by Zeeman-split levels of an atom or nucleus in a magnetic field, was a landmark in modern magnetism. Significant mainly for the insight provided into solids and liquids at an atomic scale, electron paramagnetic resonance (EPR) and nuclear magnetic resonance (NMR) spectroscopies were later complemented by that provided by the Mössbauer effect in 1958. Hyperfine interactions of nuclei and electrons provided a point probe of electric and magnetic fields at the center of the atom. In a magnetically-ordered state, precession of the magnetic sublattices in a field leads to ferromagnetic resonance (FMR) at the Larmor precession frequency of 28 GHz T^{-1} . The ability to measure the response of materials short timescales when they are out of equilibrium has been enhanced by pump/probe methods involving short intense, sub-ns pulses of energy from lasers or particle beams. Some of the methods involve special large-scale facilities, to which many users have access to supplement the facilities in their home laboratories. Communications among academic researchers intensified in the modern period—electronic communications have replaced postal reprint requests, and the scientific literature has become increasingly accessible. Collaboration between laboratories to address a particular problem as effectively as possible is increasingly common.

Of the new experimental probes of magnetism, neutron scattering was initially the most influential and generally useful. A beam of thermal neutrons from a nuclear reactor was first exploited for neutron diffraction by Clifford Shull and Ernest Wohlan in 1951, who used the magnetic scattering to reveal the antiferromagnetic order in MnO. Countless magnetic structures have been measured since, using specially-constructed research reactors at Chalk River, Harwell, Brookhaven, Grenoble and elsewhere. Excitations could be characterized by inelastic scattering of thermal neutrons, with the help of the three-axis spectrometer developed by Bertram Brockhouse in Canada to measure the change of energy and momentum. Complete spin-wave dispersion relations were used to provide a wealth of information on anisotropy and exchange. Spallation sources at Oak Ridge and elsewhere, which provide intense pulses of neutrons by collision of highly energetic protons with a target of a heavy metal such as tungsten, are most useful for studying magnetization dynamics.

Other beams produced at large-scale facilities that proved useful for probing magnetism were muons and especially synchrotron radiation. The intense, tunable ultraviolet and X-ray radiation from the circulating electrons in a synchrotron allows the measurement of magnetic dichroism from deep atomic levels, permitting the separate determination of spin and orbital contributions to the magnetic moment by X-ray circular dichroism. The intensity of the radiation from synchrotrons and free-electron lasers is greatly enhanced by arrays of permanent magnets around the beam known as undulators or wigglers, that generate intense coherent or incoherent radiation, respectively. Bending electromagnets are used to direct and focus the charged particle beams.

Direct imaging of domain structures at surfaces or in thin films with light, electron microscopy or scanning probe, magnetic-force microscopy have all contributed to an improved understanding of micromagnetics. Bulk domain structures can be accessed, with difficulty, by neutron tomography. X-ray photo-electron microscopy offers fast time-resolved imaging of domains in thin films.

Increasing availability of commercial superconducting magnets from the late 1960s has led to a boom in diagnostic imaging of tissue based on pulsed proton NMR in magnetic fields of 1–3 T. Tens of thousands of these scanners in hospitals across the world provide images of hearts, brains and every sort of tumor. Superconducting magnets can now provide fields of over 20 T for NMR and general laboratory use. Coupled with SQUID sensors, ultrasensitive magnetometers capable of measuring magnetic moments of 10^{-11} Am^2 are widely available. Larger fields of up to 30 T require expensive special installations with water-cooled Bitter magnets consuming many megawatts of electrical power. Resistive/superconducting hybrids in Tallahassee, Grenoble and Tokyo can generate steady fields in excess of 40 T. Still higher fields above 50 T demand millisecond pulses; the higher the field, the shorter the pulse; 200 T can be reached in small volumes with a single turn sacrificial coil. Even greater transient fields can be attained by explosive flux compression.

Materials and technology

For many physical studies, magnetic materials are needed in special forms, such as single crystals or thin films. Skilled crystal-growers are assiduously cultivated by neutron scatterers and other condensed matter physicists. With large crystals, tensor properties such as susceptibility, magnetostriction and magnetotransport can be measured in any direction.

A far-reaching advance after 1970 was the appearance of multi-target thin-film growth facilities (sputtering, pulsed-laser deposition, molecular-beam epitaxy) in magnetism research laboratories. Ultra-high vacuum facilitated the study of surface magnetism at an atomic level, but much of the motivation was to investigate magnetoresistance or magneto-optics or of thin, high-quality metal films, and especially the thin film multilayer structures that have contributed massively to the development of spintronics and magnetic data storage. An example of a fairly complex stack that, after suitable heat treatment, exhibits perpendicular magnetic anisotropy and 200% tunnelling magnetoresistance (TMR) is illustrated in Fig. 12.

Conventional electronics ignored the spin of the electron because unlike electron charge, electron spin is not necessarily conserved in scattering events. A conduction electron in a metal may undergo 100 scattering events before a spin flip. If the mean free path is 2 nm it will only have travelled about 12 nm before losing its spin memory. Unpolarized electrons acquire a spin polarization on traversing a couple of nanometers of cobalt, but the spin-polarized current does not go far in an insulator or nonmagnetic metal before losing its spin memory. Hence the choice of materials in a stack and their thickness is critical. Layers of an antiferromagnet such as IrMn_3 are used for exchange bias to pin the magnetization of an adjacent ferromagnetic layer in spin valves

Fig. 12 A thin film stack with a magnetic tunnel junction (left). The magnetic layer below the MgO tunnel barrier is pinned by coupling to the antiferromagnetic IrMn₃ layer to produce the magnetoresistance characteristic (right).

from the mid-1990s. The anisotropic magnetoresistance $\approx 1\%$ (AMR) of single a layer of permalloy was used for the first sensors or memory elements in the 1980s. A sandwich spin-valve structure with a nonmagnetic metal spacer layer that exhibited giant magnetoresistance $\approx 10\%$ (GMR) was more versatile, with fixed and pinned layers oriented parallel for a switchable memory element and perpendicular for a linear field sensor. The moments were oriented in-plane in the first devices and perpendicular to the plane in later ones. Greater sensitivity was achieved in spin valves with an insulating tunnel barrier of amorphous AlO_x or crystalline MgO where greater tunnel magnetoresistance $\approx 200\%$ could be achieved. The timeline for the adoptions of these sensors in read heads for magnetic recording where they have to read the stray fields just above the disc surface is illustrated in Fig. 13. The writer has always been a miniature electromagnet. The sensors, originally designed for magnetic recording, found important applications in partnership with magnetic nanoparticles in bio-assay.

The development of non-volatile thin film memory underwent a similar evolution beginning with thin film permalloy memory with a lattice of current carrying wires to create local magnetic fields sufficient to switch the bits, analogous to ferrite cores, in the 1960s. Then, after the discovery of giant magnetoresistance by Albert Fert, Peter Grunberg and others in 1988, spin valve memories based on half-select magnetic field toggle switching appeared in the 1990s. The field switching was not scalable, so a new generation of spin-transfer torque magnetic random-access memory developed around 2010 used the angular momentum of a spin-polarized current passing perpendicular to the stack to switch the free layer. In suitable conditions, the switch becomes an oscillator.

Fig. 13 Exponential growth of magnetic recording density over 60 years, with an illustration of the read/write technology.

The spin Hall effect, rediscovered in 1999 by Jaime Hirsch, is the creation of a transverse spin current flowing perpendicular to a charge current in a heavy metal, due to spin-orbit scattering. It is harnessed in heavy metal/ferromagnetic bilayers to inject angular momentum into the ferromagnet and switch its magnetization by 'spin-orbit torque', another potential scheme for magnetic memory. Magnetic recording and spin electronics became major research preoccupations in the magnetic research community after about 1990. A cognate growing discipline is magnonics, where spin waves rather than electrons are used to transmit and process data.

A quite different, earlier preoccupation arose from studies of phase transitions in model magnetic systems in the 1970s, namely the effect of atomic disorder and the absence of a crystalline lattice on magnetic order. A seed was sown by Pol Duwez in 1960 who first produced small samples of amorphous metal by splat cooling, but applications became feasible only after the invention in 1976 of continuous melt spinning, where a jet of molten metal impinges on a copper wheel rotating with a surface velocity of about 50 ms^{-1} to give a quench rate of up to 10^6 K s^{-1} , sufficient to freeze eutectic metallic melts into amorphous solids. Other melts such as Nd—Fe—B became nanocrystalline. The first soft magnetic amorphous materials $\text{Fe}_{80}(\text{P,B,C})_{20}$ were spun in 1976 by Robert O'Handley and Ryusuke Hazegawa and a range of Fe—Co- and FeNi-based alloys were subsequently commercialized in the 1980s by Allied Chemical as *Metglas*. The amorphous alloys found niche markets in network transformers, components for power electronics and many kinds of magnetic sensors due to their exceptional magnetic softness. A parallel discovery made at Hitachi Metals by Yoshihito Yoshisawa in 1988 while trying to lower high frequency losses by pinning domain walls with micro-size crystallites was *Finemet*, a Fe—Si—B—Nb alloy with 1% of copper. This material is a composite of nanocrystals of Fe—Si in an amorphous matrix. It combines polarization of 1.25 T, larger than permalloy, and is as soft as cobalt based amorphous alloys, yet uses no cobalt. The astonishing softness of nanocrystalline materials was explained a year later by Gisela Herzer at Vacuumschmelze, where similar alloys were developed.

Perhaps the most far-reaching advances in bulk magnetic materials for electromagnetic applications in the modern period was the invention and development of rare earth permanent magnets. They are more expensive to make than hard ferrites, but they offer stored energy densities that are an order of magnitude greater. First were magnets based on the binary intermetallic phases SmCo_5 or $\text{Sm}_2\text{Co}_{17}$ that were pioneered by Karl Strnat in the 1960s. A global cobalt supply crisis brought about by war in Zaire in 1979, led to a renewed effort to find an Fe-based substitute, which bore fruit in 1983 in two different ways. First was the discovery by Masato Sagawa at Sumitomo Special Metals of $\text{Nd}_2\text{Fe}_{14}\text{B}$, a tetragonal iron-rich interstitial phase with boron, using the methods of classic powder metallurgy. Favorable phase relations included a low-melting nonmagnetic Nd-rich phase that surrounded the $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains and facilitated the development of coercivity. The properties were continuously improved over the following years with additives of Co or heavy rare earths (Dy, Tb) and optimized crystallite orientation and milling to increase the volume fraction and reduce the size of the hard magnetic crystallites. Many grades became available with a trade-off between remanence and coercivity, which determines the maximum operating temperature.

A different approach was adopted by John Croat at General Motors, who used melt spinning to produce isotropic nanocrystalline material that was useful for making polymer bonded material by injection or compression molding. These have lower energy products than sintered magnet, but great flexibility for manufacture of components in complex shapes.

Nd—Fe—B magnets have grown to dominate the permanent magnet market. They radically changed the design of motors for many applications. They were indispensable for the voice-coil motors in slim hard-disc drives and enhanced considerably the power density of small motors—a quadcopter could not take off without NdFeB magnets. They improve the efficiency of high-power electrical machines and applications are burgeoning in new areas of motors for electric vehicles and robotics, and in large direct-drive wind turbines now seen in landscapes everywhere.

In summary, the consequences of near-instantaneous access to virtually unlimited stores of magnetically recorded data in centers distributed across the world, and the ability to acquire and copy it electronically at practically no cost to the user is the basis of the 'big data' revolution that we are in the midst of. However, the quantities of data are so enormous that energy costs are exploding and may become prohibitive. The implications for human life and society are unpredictable but are likely to be as profound as on the previous two occasions when magnetism changed the World.

Conclusion

Past record is no guarantee of future performance, so one must be wary of extrapolating the history of any science or technology very far into the future. Magnetism, like much of physics itself, has often been dismissed as 'finished' in the past, only to confound the doomsayers with some new twist or unexpected development. The current focus on spin electronics and nanoscale magnetism in artificially-structured thin film devices will surely be sustained for some time to come.

The behavior of magnetism on increasingly short timescales, the influence of topology in normal and reciprocal space, and information transfer and processing using magnons rather than spin directly are topics that seem likely to attract continued research interest.

Industrial applications of magnetism are largely based on the properties of about a dozen commercially-produced magnetic materials. The discovery of just one more could animate the subject for a decade. It seems unlikely, though, that much advance will be achieved on the magnetic values on the hysteresis loop. There has been no advance in saturation magnetization in a century over that of $\text{Fe}_{35}\text{Co}_{65}$, and coercivity can already be controlled, albeit with much care and effort, to almost any desired value. No Curie

temperature has ever exceeded that of cobalt, which has been known since 1912. The new material will probably commend itself by a useful combination of magnetic and nonmagnetic (electrical, optical, mechanical, thermal) properties.

Magnetism has served the miniaturization of information technology and electromagnetic drives well and may continue to do so in future. New frontiers in cell biology have to be explored. Applications of magnetic nanoparticles in medicine are burgeoning. There have been half a dozen paradigm shifts—completely new ways of seeing the magnet and its field—during the 3000 years encounter of magnetism with human curiosity. Magnetism has effectively transformed the world on three occasions; who can say there will not be another?

Abstract

Amorphous metallic magnets, spin glasses and dense magnetic nanoparticle systems are systems where interaction between magnetic moments cause collective magnetic ordering in spite of disordered atomic or particle structure. Disordered spin-structures provide model systems, such as spin glasses and random field systems, of large interest for fundamental research. Disorder of the atomic structures of ferromagnets govern their coercivity and determine the quality of both soft and hard magnetic materials in applications.

Key points

- Models and magnetic properties of spin glasses and superspin glasses
- Descriptions of properties and models of random field Ising systems.
- Models and phase diagrams of reentrant spin glasses.
- Properties of amorphous magnetic systems.
- Effects of disorder on soft and hard ferromagnets.

Nomenclature

T	Temperature [K]
T_g	Spin glass temperature [K]
T_f	Freezing temperature [K]
t	Reduced temperature
t	Time [s]
t_w	Wait time [s]
τ	Relaxation time [s]
f	Frequency [Hz]
H	Magnetic field [Am^{-1}]
h	Magnetic field [Am^{-1}]
M	Magnetisation [Am^{-1}] alt. [a.u.]
χ	Magnetic susceptibility [SI] alt. [a.u.]
S	Spin
J	Exchange interaction
FC	Field cooled
ZFC	Zero field cooled

[☆]*Change History:* February 2023. P Nordblad has been involved in the update. The section on Re-entrant spin glasses has been revised and Fig. 3 added. Recent references have been added: Kawamura and Taniguchi (2015), Mydosh (2015), Parisi (2021), Peddis et al. (2021).

Introduction

The subject disordered magnetic systems comprise, when defined widely, the whole field of applied magnetic materials, ranging from extremely soft Permalloy to the hardest permanent magnet; as well as the physics of model systems of strongly disordered magnetic materials: Spin glasses and random field Ising systems (Young, 1998).

Magnetic ordering requires that the electron system forms local or itinerant magnetic moments and that there is interaction between these moments. Such interacting magnetic moments will eventually, as the temperature is lowered, become correlated and in certain cases form a long ranged ordered phase at a critical temperature. The simplest magnetic order in crystalline systems arises when the leading interaction is ferromagnetic and there is only one type of magnetic ions in the material. The low temperature phase then shows a regular pattern with the magnetic moments all aligned in parallel. Magnetic disorder in an ideal system of this type is enforced by thermal energy and above the critical ordering temperature, a random paramagnetic phase forms. However, intrinsic quenched disorder, due to lattice dislocations, impurities, and other defects, always appear in a real magnetic system, also in the magnetically ordered phase. This kind of disorder is the key to the macroscopic magnetic properties of an ordered ferromagnet. The disorder and the microstructure of the system then determine if a weakly anisotropic magnet becomes a good soft ferromagnet or if a strongly anisotropic system attains applicable permanent magnet properties. It is thus disorder, on nano- and micrometer length scales, that governs the quality of applied magnetic materials, whether soft or hard.

Models

A random distribution of the atomic magnetic elements in alloys and compounds introduces strong disorder and deviations from a regular interaction pattern. The interaction in-between the magnetic constituents become random in size and in cases also in sign. This causes the appearance of new magnetic phases and phenomena. An interacting magnetic Ising system can be described by its spin Hamiltonian:

$$H = - \sum_{i,j} J_{ij} S_i S_j \quad (1)$$

where J_{ij} is the exchange interaction strength between spin S_i and spin S_j ; spins that in an Ising system point either up or down. A random exchange ferromagnet is described if all J_{ij} are positive but of different magnitude and a spin glass is described if the sign of J_{ij} varies but the mean value is zero (Fisher and Hertz, 1991; Mydosh, 2015). Eq. (1) can be used to describe systems of any dimensionality and any range of interaction. Another important class of disordered magnetic Ising systems is the random field system:

$$H = - \sum_{i,j} J_{ij} S_i S_j + \sum_i h_i S_i \quad (2)$$

where J_{ij} are positive interaction constants and h_i is a local field of random size and sign with zero mean that acts on spin number S_i . This system does not have an experimental realization, but a dilute Ising antiferromagnet in an applied homogeneous magnetic field has been shown to describe an equivalent problem:

$$H = - \sum_{i,j} J_{ij} S_i S_j + H_a \sum_i \varepsilon_i S_i \quad (3)$$

where J is a negative exchange interaction constant and ε_i is 1 if site i is occupied by a magnetic ion and 0 if the site contains a nonmagnetic element. H_a represents a homogeneous applied magnetic field, and the equation shows that the random field is proportional to this field and thus arbitrarily tunable (Belanger and Young, 1991).

Spin glasses

An alloy with magnetic ions randomly dispersed in a nonmagnetic host metal forms at low magnetic ion concentrations an archetypical spin glass material. The interaction in the system is random in size and sign due to the Ruderman-Kittel-Kasuya-Yosida (RKKY) nature of the interaction in a metal. The RKKY-interaction is mediated by the conduction electrons and is oscillatory in size and decays with the cube of the distance in-between the magnetic constituents. The signature and the initial cause of interest in this type of dilute magnetic alloys was the observation of a cusp in the in-phase component of the ac-susceptibility by Cannella and Mydosh (1972). This finding was a clear indication of a phase transition to a new kind of magnetic order and this phase, later named the spin glass phase, has been found to own surprising magnetic properties and has created a theoretical problem of much greater complexity than only a cusp in the ac-susceptibility gave promise to Mezard et al. (1987), Mydosh (2015), Nordblad (2013), Kawamura and Taniguchi (2015) and Stein and Newman (2013). Spin glasses provide a useful introduction to the physics of strongly disorder magnetic systems in general and are therefore described in some detail below.

A spin glass problem can be defined using Eq. (1) and setting the spatial dimension of the system as well as the distribution and range of the interaction J_{ij} . In the Sherrington-Kirkpatrick (SK) model (Sherrington and Kirkpatrick, 1975), the sum is taken over all pairs (i,j) of N spins and a Gaussian distribution of J_{ij} with zero mean is used. The famous Parisi solution of this problem using replica symmetry breaking (RSB) forms one school of models describing spin glasses: The RSB or mean field picture (Mezard et al., 1984). An alternative model to describe finite dimensional systems is the droplet picture, which is based on the scaling hypothesis and yields a spin glass with, in parts, remarkably different properties than the mean field predictions. A main difference concerns the nature of the spin glass in a magnetic field, where the droplet picture prescribes that there is no equilibrium spin glass phase, whereas the RSB model yields a phase line in the field-temperature (H - T) plane (the Almeida-Thouless line) that separates the paramagnetic from the spin glass phase. On the other hand, in zero magnetic fields, both models anticipate a low temperature phase with relaxation processes that lasts over exceedingly wide time scales and a non-stationary nature of a system that has been quenched to a temperature below its spin glass temperature (T_g).

There is an extensive literature on the static and dynamic magnetic properties of three-dimensional spin glass materials as observed in experiments and Monte Carlo (MC) simulations on three dimensional Ising spin glass models. A quite clear empirical picture as to the magnetic properties of spin glasses can be extracted from this literature. The behavior is however complex and has allowed interpretations in terms of both the RSB and the droplet scaling model or combinations of the two pictures.

It is firmly established that there is a second order phase transition to a low temperature spin glass phase in zero field. This transition is evidenced from the dynamics through analyses of the critical slowing down on approaching the phase transition temperature (spin glass temperature) and from the static susceptibility through a divergence of the non-linear susceptibility on approaching T_g . In Fig. 1, ac-susceptibility data at different frequencies measured on the Ising spin glass $\text{Fe}_{0.5}\text{Mn}_{0.5}\text{TiO}_3$ are shown; the original spin glass signature: A (frequency dependent) cusp in the ac-susceptibility is clearly seen. The temperature dependence of the relaxation time, τ , that can be derived from the frequency dependence of the cusp (or freezing) temperature, T_f , obeys critical slowing down and implies a phase transition with a relaxation time that diverges according to critical slowing down: $\tau = \tau_0 t^{-zv}$, where τ_0 is an atomic relaxation time of order 10^{-13} s, $zv \approx 10$ is the dynamic critical exponent and t is the reduced temperature, $t = T/T_g - 1$. Critical slowing down and the existence of a low temperature spin glass phase has convincingly been established from experiments and simulations on three dimensional Ising spin glasses. This is one side of the phase transition problem; a key question, which distinguishes the RSB- and droplet model predictions, is whether the phase transition persists in an applied magnetic field or not. This seemingly simple question has not been easy to answer from either experiments or simulations. However, analyses of the in-field dynamics of the Ising spin glass $\text{Fe}_{0.5}\text{Mn}_{0.5}\text{TiO}_3$ show that the slowing down of the relaxation time is significantly altered in an applied field compared to zero field and suggest that there is no phase transition in a magnetic field in a three-dimensional Ising spin glass.

The response of a spin glass to the application of a weak magnetic field in the spin glass phase extends from the atomic relaxation time (τ_0) to exceedingly long times well beyond the time scale of any experimental probe., i.e., in common with other glassy systems, the relaxation times are exceedingly long in the low temperature phase. Also, in common with other glasses, the low temperature spin glass falls out of equilibrium as the system is cooled through the spin glass transition temperature. Once the system is kept at constant temperature in the low temperature phase, it spontaneously and continuously reorganizes the spin structure—the system ages! Aging has a very characteristic influence on the response function of spin glasses. The relaxation of the magnetization $M(t)$ attains an inflection point at an observation time (t) of the order of the wait time (t_w) at constant temperature before the weak magnetic field was applied in a plot of $M(t)$ vs. $\log(t)$. Fig. 2a shows the relaxation of the magnetization $M(t)$ of a Ag(11 at.% Mn) spin glass measured after the different wait times indicated in the figure; also plotted in the figure is the relaxation

Fig. 1 The ac-susceptibility, $\chi'(f, T)$, measured along the c-axis of the Ising spin glass, $\text{Fe}_{0.5}\text{Mn}_{0.5}\text{TiO}_3$. The frequency (f) of the weak ac-field is indicated in the figure. Fig. 2 (a) The left figure shows the relaxation of the zero field cooled magnetization $M(t)$ of the spin glass Ag(11 at.% Mn) at $T = 30$ K. The magnetization has been measured after different wait times at the measurement temperature as indicated in the figure. The right figure shows the relaxation rate $S(t) = \partial M(t)/\partial \log(t)$ of the magnetization relaxation curves. $T_g \approx 32$ K, $h = 40$ Am $^{-1}$. (b) ZFC and FC magnetization vs. temperature ($M(T)/H$) for the spin glass Ag(11 at.% Mn). The curve labeled ZFC-ref shows the ZFC-magnetization measured after continuous cooling to low temperature, whereas the curve labeled ZFC-mem shows the corresponding curve measured after the sample has been kept at 27 K for 10^4 s during otherwise continuous cooling. $H = 8$ Am $^{-1}$. Panel (a): Data from Jönsson P (2002) Anisotropy, disorder and frustration in magnetic nanoparticle systems and spin glasses. *Comprehensive summaries of Uppsala dissertations from the Faculty of Science and Technology* 727, *Acta Universitatis Uppsaliensis*, panel (b): Data from Mathieu R (2002) Magnetism of manganites, semiconductors and spin glasses. *Uppsala dissertations from the Faculty of Science and Technology* 38, *Acta Universitatis Uppsaliensis*.

rate, $S(t) = \partial M(t)/\partial \log(t)$, i.e., the local slope of the relaxation curves; this quantity exhibits a pronounced maximum at an observation time equal to the wait time. Results from Monte Carlo (MC) simulations of the dynamics of three-dimensional Ising spin glass models yield similar results and confirm the existence of an aging phenomenon. A main conclusion from the aging (non-equilibrium) behavior is that the spin glass continuously evolves toward an equilibrium state at constant temperature in the spin glass phase and that this equilibrium state is different at different temperatures (the system appears chaotic).

An additional and remarkable feature of the non-equilibrium spin glass phase is that it incorporates a memory phenomenon. This phenomenon is most simply revealed by measurements according to a standard protocol to investigate the temperature dependence and irreversibility of the magnetization through the phase transition temperature of a magnetic system. The zero-field-cooled (ZFC) and field-cooled (FC) magnetization, which are measured by cooling the sample in zero field, apply a weak field at a low temperature and record the magnetization (ZFC) while continuously heating the system to a temperature above T_g and then re-cool the magnetization in the applied field while recording the magnetization (FC). Such magnetization curves are shown for the archetypical spin glass Ag(11 at.% Mn) in Fig. 2b. In addition, the figure shows a magnetization curve where the cooling of the sample has been interrupted for some hours at 27 K, and after reaching the low temperature, the magnetization was recorded on continuous heating in the same way as the ZFC-reference curve. This ZFC-mem curve shows a pronounced dip at the temperature for the stop. The system keeps a memory of the cooling history—and the memory is recalled when recording the ZFC magnetization on re-heating the spin glass. The observed dip in the ZFC-mem curve is reminiscent of the aging that occurs in the system when it is kept at constant temperature, which results in a slower relaxation with increasing age of the system as was illustrated in Fig. 2a. The memory-aging behavior are manifestations of some crucial concepts—aging, rejuvenation and chaos—that characterize the spin glass phase and are of key importance for the modeling spin glasses.

Spin glass behavior is not only confined to the model systems, with atomic magnetic moments, described above; there are several other disordered magnetic systems that have been found to show spin glass like magnetic behavior, e.g.: Interacting magnetic nanoparticle systems (superspin glasses) (Peddis et al., 2021), granular magnetic systems, some manganites and cobaltites and certain high temperature superconductors.

Re-entrant spin glasses

A spin glass is formed when there is disorder and frustration due to an equal amount of positive and negative interactions in the system, i.e., the mean value of the interactions is close to zero. Such systems can simply be modeled by using an equal amount of interactions of the same magnitude $\pm J$ in the system or by using a Gaussian distribution of the interactions with zero mean. If the random interactions have a non-zero mean value, ferro (+) or antiferromagnetic (−), the system can show re-entrant behavior. The system first orders according to the dominant interaction at a high temperature and forms a long ranged ordered random ferromagnetic or antiferromagnetic phase, cf. the phase diagram in Fig. 3, where in the concentration range 15–24%, the system on cooling first enters a ferromagnetic phase and at a lower temperature reaches a re-entrant spin glass phase (RSG). However, on further lowering the temperature, the system seems to re-enter into a disordered phase, a spin glass phase. Re-entrant systems are quite common; they appear, e.g., at higher concentration of magnetic atoms in dilute magnetic alloys and amorphous metals. Re-entrant ferromagnets show some remarkable properties: Both the re-entrant spin glass phase and the long range ordered phase show an aging phenomenon and on cooling into the low temperature spin glass phase the ferromagnetic long range order seem to persist although macroscopic ac-susceptibility data indicate critical slowing down and a true re-entrance into a spin glass phase. Many unanswered questions remain as to the physics of re-entrant magnetic systems.

The random field Ising model

A random field Ising system is described by Eq. (2). The properties of that Hamiltonian has been extensively studied theoretically and by simulations and has been found to show a behavior that is very different from a random exchange or pure ferromagnetic system with respect to critical exponents, critical dimensions, and magnetic properties. Experimentally, there is no real material that provides local random fields as prescribed by the random field Ising model. However, the random field Hamiltonian is mapped by a dilute antiferromagnet in a homogeneous magnetic field: Eq. (3) above—and such materials are readily fabricated in single crystalline form and provide systems that allow a continuously tunable strength of the random field only by varying the strength of an applied homogeneous magnetic field. A major part of the experimental work on three-dimensional random field magnetic systems has been performed on the model Ising antiferromagnetic system FeF_2 diluted with non-magnetic zinc atoms: $\text{Fe}_{1-x}\text{Zn}_x\text{F}_2$ (Belanger, 2000). The study of random field systems is made more complicated by nonequilibrium effects that appear when the system is cooled to low temperatures and hinder the system to reach thermodynamic equilibrium. A quite consistent

Fig. 3 A schematic phase diagram of a dilute metallic alloy where the concentration (x (at. %)) of magnetic ions increases from 0 to 36%. The alloy is paramagnetic (PM) at high temperatures, a spin glass (SG) at low temperatures and low concentration ($<16\%$) of magnetic ions, ferromagnetic (FM) at low temperatures and high concentration of magnetic ions and finally a re-entrant spin glass (RSG) at low temperatures and concentration $16 < x < 24$.

picture as to some thermodynamic equilibrium properties of random field systems of different spatial dimensionality has however been empirically attained.

The two-dimensional Ising system forms a low temperature ordered phase via a second order phase transition, the only second order phase transition that has been given an exact solution (Onsager, 1944). This transition is, both in theory and experiments, found to be destroyed by finite random fields, i.e., the lower critical dimension of the random field Ising system is two or larger. In 3d random field Ising systems, it has, after many years of experimental and theoretical controversies, been confirmed that the second order phase transition survives in random fields and both theory and experiments agree that the lower critical dimension is equal to two. The critical exponents describing the asymptotic behavior at the phase transition are significantly different from those of the pure three-dimensional Ising and also different from the random exchange Ising model values.

Nonequilibrium effects appear as the random field system is cooled into the ordered phase and cause the occurrence of domain states and relaxation phenomena that are not yet fully satisfactory described by theory and experiments. However, a quite high level of empirical understanding of the physics of random field Ising model systems has been realized by combining results from macroscopic (susceptibility, magnetization, and specific heat) measurements with results from microscopic probes (neutron scattering and X-ray scattering experiments).

Amorphous magnetic systems

Crystallographically disordered materials with an exchange interaction strength that is dependent on the distance between the magnetic entities would naturally form disordered magnetic systems that mimic a random exchange or more complicated model system. A realization of such systems is amorphous metals fabricated by rapid quenching methods and stabilized by introducing glass forming elements in the melt. Magnetic metallic glasses were first fabricated in the late 1960s and early 1970s and have provided excellent model systems for disordered magnetic systems and the influence of random exchange on the magnetic properties. There are outstanding possibilities to tailor materials using the rapid quench method, since almost any composition of different metals can be mixed without a need to consider phase segregation or consult complicated phase diagrams. It was early found that amorphous magnetic metals can form a variety of magnetic structures: Ranging from simple ferromagnets to complex ferrimagnetic spiral structures and spin glasses. However, a huge challenge and obstacle for the theoretical description of these metals is of course the lack of a periodic lattice as a backbone for the description of the electronic structure (Burton, 2013; Hansen, 1991; Hasegawa, 1991; Luborsky, 1980).

Amorphous metals are trapped in a metastable state and the structure has to be stabilized against crystallization, which severely limits the possible production processes. However, an important part of the interest in amorphous magnetic metals is due to their potential as magnetic materials in many applications. The possibility to fabricate materials with marginal magnetocrystalline anisotropy, very low magnetostriction and high resistivity compared to their crystalline counterparts promises materials with excellent soft magnetic properties for medium and high frequency applications and soft amorphous magnetic metal systems have also found important applications in, e.g., small-scale transformers, motors, and generators. The rapid quenching method does not only allow amorphous metals to form—it also yields possibilities to fabricate nano crystalline systems. Systems, which at certain microstructure sizes, form extremely hard magnetic materials with exceedingly high coercivity (which are useful building blocks for good permanent magnets) whereas they at other compositions and nano crystalline sizes provide materials with excellent soft magnetic properties (Herzer, 1997).

Magnetic materials

Disorder is the physical parameter that governs extrinsic magnetic properties, such as coercivity, remanence and energy product, of an intrinsically ferromagnetic or ferrimagnetic material. The producer of magnetic materials is thus forced to understand disorder to be able to effectively design and fabricate both soft and hard magnetic materials. It is in fact the ability to master disorder and find new material combinations that underlies the fast improvement of the technical performance that magnetic materials have been subject to during the last few decades. Maybe the prime example of such progress is found in the rapidly increasing areal storage density that magnetic information storage media has undergone and continuously is experiencing.

Conclusion

Theoretical and experimental studies of disordered magnetic model systems such as the Ising spin glass and the random field Ising model have provided new insights and understanding of the influence of disorder on the properties of not only magnetic but also other physical systems. In addition, the models and methods that have been developed in this research have found applications in many different fields of science that deal with complex and disordered systems: Examples are found in the physics of ordinary glasses and in optimization problems as well as in studies of stock markets and descriptions of social systems. The pioneering work of Prof. Giorgio Parisi in this field of science was awarded the Nobel Prize in Physics in 2021 (Parisi, 2021).

Nomenclature

$\mathcal{B}$	Brillouin function
C	Curie constant
g_J	Landé factor
H_{app}	applied magnetic field (vector)
H_{app}	applied magnetic field (magnitude)
H_{m}	molecular field
J	exchange integral
J	total angular momentum
k_0	propagation vector
l	orbital quantum number
l	orbital momentum
$\mathcal{L}$	Langevin function
L	orbital momentum
m	magnetic quantum number
m_0	measured magnetic moment at 0 – K
m	magnetic moment
m_l	orbital moment
m_s	spin moment
m_z	projection of m along H_{app}
M	magnetization
M_s	spontaneous magnetization
$M_{s,0}$	magnetization at absolute saturation
n	molecular field coefficient
N	number of moments per unit volume
N_D	demagnetizing field coefficient
N_T	total number of moments

[☆]*Change History:* May 2015. T. Takabatake revised the last paragraph 'Experimental Studies of Magnetic Structures' and 'Further Readings'.

S	spin or spin angular momentum
T	temperature
T_c	critical temperature
T_C	Curie temperature
T_N	Néel temperature
v_{at}	atom volume
x	argument of the Langevin or Brillouin function
z	number of first neighbors
χ	magnetic susceptibility
μ_B	Bohr magneton
μ_{eff}	effective moment
μ_0	permittivity of vacuum

Introduction

Magnetism is a property of electrons within matter. Strong interactions exist between the atomic magnetic moments; they are of electrostatic origin, and are termed exchange interactions.

In the simplest case, the exchange interactions favor parallelism of all magnetic moments; this leads to ferromagnetic order. The properties of ferromagnetic materials can be described within the molecular field model. However, the experiment provides evidence for the local character of the interactions which cannot be explained within this model.

More generally, the exchange interactions may favor different types of coupling, and a large variety of different magnetic structures may exist. In the antiferromagnetic structures, the moments are arranged in two groups, termed sublattices. Within each sublattice, the moments are parallel, but they are antiparallel to the moments in the other sublattice. In many instances, the magnetic structure results from a competition between different interactions which cannot be satisfied simultaneously. This is, in particular, the case of the helimagnetic and modulated structures. When the arrangement of the magnetic atoms themselves is not periodic, spin-glass arrangements are found.

The most powerful technique for the study of magnetic structures is neutron diffraction, in which the neutron magnetic moment is used to probe the arrangement of the atomic moments.

Magnetic Moment and Magnetic Field

Magnetic Moment

Within matter, magnetism is due to electron motion around the nuclei. There are two contributions to the magnetic moment of an electron:

- The orbital moment, m_l , is linked to the motion of the electrons in their orbits. It may be expressed as $m_l = -\mu_B l$, where l is the orbital momentum and μ_B , the Bohr magneton, is the fundamental unit of magnetic moments ($1\mu_B = 0.927 \times 10^{-23} \text{ A m}^2$). The quantum mechanical eigenvalues of $\langle l^2 \rangle$ are equal to $l(l+1)$ where l is an integer, called the orbital quantum number. The values $l=0, 1, 2$, and 3 are associated to electrons of the s, p, d, and f shells respectively. The eigenvalues of $\langle l_z \rangle$ are integers, denoted m , where m is the magnetic quantum number; m is restricted between two limits, $+l$ and $-l$.
- The spin moment, $m_s = -\mu_B s$ is related to the electron spin momentum, s , most often referred to as the 'spin.' The spin is an entity of purely quantum mechanical nature. The eigenvalues of $\langle s^2 \rangle$ are equal to $s(s+1)$, where s , the spin quantum number, equal to $1/2$. The eigenvalue of $\langle s_z \rangle$ are $+1/2$ and $-1/2$.

Due to the electrostatic interactions existing between electrons located on the same electronic shell of a given atom, the spin and orbital momentum of individual electrons are coupled together, according to the so-called Hund's rules. The resulting orbital momentum of the considered shell is noted as L , and the resulting spin, S . L and S are strongly coupled together by the spin-orbit coupling. For a full electronic shell, $L = 0$ and $S = 0$; magnetism is a property of partly filled electronic shells.

In the solid state, only two series of stable elements may show spontaneous magnetism (the actinides may be magnetic as well).

1. In the 3d transition series, to which Fe, Co, and Ni belong, magnetism is due to the progressive filling of the 3d shell. The orbital momentum is almost quenched. In the case where the 3d electrons are localized, the maximum value of the magnetic moment is approximately equal to $-2\mu_B S$. In 3d metallic systems, the magnetic 3d electrons have a certain itinerant character. The magnetic moments, expressed in μ_B , take a fractional value, which cannot be derived by the present simple considerations.
2. In the rare-earth series, from cerium to lutetium, magnetism results from the progressive filling of the 4f shells. The 4f electrons are fully localized. The maximum value of the moment is equal to $-g\mu_B J$, where J is equal to $L+S$ or $L-S$, depending on the considered element and g_J is the Landé factor.

Another magnetic moment may exist within matter, associated to the constitutive elements of the nucleus. The proton moment, μ_p , and the neutron moment, μ_n , amount to $\mu_B/657$ and $\mu_B/959$ respectively.

Magnetic Moments in a Magnetic Field – Paramagnetism

When submitted to an applied magnetic field, H_{app} , a magnetic moment, $\mathbf{m}$, tends to align along the field direction. The corresponding energy, called Zeeman energy, e_Z , is

$$e_Z = -\mu_0 \mathbf{m} \cdot \mathbf{H}_{\text{app}} \quad [1]$$

An assembly of moments, $\mathbf{m}$, may be characterized by the magnetization, M , which is the moment per unit volume measured along the field direction, z :

$$M = N \langle m_z \rangle_T \quad [2]$$

where N is the number of moments per unit volume and $\langle m_z \rangle_T$ is the thermal averaged value of m_z , the projection of $\mathbf{m}$ along H_{app} .

At finite temperature, moment alignment is in competition with thermal activation which tends to create disorder; this characterizes paramagnetism. For a system of classical noninteracting moments, the magnetization, M , is given by

$$M = N m_0 \mathcal{L}(x) \quad [3]$$

In [expression \[3\]](#), m_0 is the value of the moment at 0 K and $\mathcal{L}(x) = \coth(x) - 1/x$ is the Langevin function. The parameter x which enters into the Langevin function is the ratio between Zeeman energy and thermal energy:

$$x = \frac{\mu_0 \mathbf{m} \cdot \mathbf{H}_{\text{app}}}{k_B T} \quad [4]$$

where μ_0 is the permittivity of vacuum ($=4\pi \times 10^{-7}$ SI) and k_B is the Boltzmann constant.

For small x , the Langevin function may be expanded as $\mathcal{L}(x) \approx x/3 - x^3/45 + \dots$. The high-temperature development of [3] is

$$M = C \frac{H_{\text{app}}}{T} \quad [5]$$

where C is the Curie constant, given by

$$C = \frac{\mu_0 N m_0^2}{3 k_B} \quad [6]$$

A useful experimental parameter is the susceptibility, $\chi = M/H_{\text{app}}$. The reciprocal susceptibility $1/\chi$ varies linearly with T , with a slope $1/C$ ([Figure 1\(a\)](#)). This constitutes the Curie law.

For systems of quantum moments, the Langevin function must be replaced by a Brillouin function, $\mathcal{B}(x)$. The moment m_0 in [expression \[3\]](#) is equal to $-2\mu_B S$ (systems in which 3d localized electrons are involved) or $-g\mu_B J$ (rare-earth-based systems), the maximum values of the projection of $\mathbf{m}$ along the field, whereas m_0 in [expression \[6\]](#) is replaced by μ_{eff} , the effective moment which is proportional to $\sqrt{S(S+1)}$ or to $\sqrt{J(J+1)}$.

Ferromagnetic Order

The Molecular Field Model

There is a category of magnetic materials, where the high-temperature susceptibility does not follow the Curie law, but is given by the expression

$$\chi = \frac{C}{T - T_C} \quad [7]$$

where T_C is the Curie temperature ([Figure 1\(a\)](#)). [Expression \[7\]](#) constitutes the Curie–Weiss law. It may be ascribed to interactions existing between the magnetic moments. To first approximation, these interactions are equivalent to a field, termed H_m , created by the magnetic moments themselves. Within the molecular field theory of ferromagnetism, H_m is assumed to be proportional to the magnetization, M :

$$H_m = nM \quad [8]$$

where n is the molecular field coefficient, such that

$$T_C = nC \quad [9]$$

The value of the magnetization M may be obtained by replacing the applied field H_{app} in [expression \[4\]](#) by $H_{\text{app}} + H_m$ and by expressing that [relations \[3\] and \[8\]](#) must be satisfied simultaneously. Consider the special case where $H_{\text{app}} = 0$. At temperatures

Figure 1 (a) In a system of noninteracting moments, the reciprocal susceptibility, $1/\chi(T)$, varies linearly with temperature with a slope $1/C$, where C is the Curie constant. In the presence of interactions, the molecular field model predicts a similar variation, but the representative curve is shifted towards higher temperatures. At $T = T_C$, the susceptibility becomes infinite. At $T < T_C$, a spontaneous magnetization, M_s , exists. This is ferromagnetism. The molecular field model does not properly give account for the existence of local fluctuations. These are responsible for the fact that the Curie temperature is lower than predicted and that the variation of $1/\chi(T)$ is not linear in the vicinity of T_C . (b) In an antiferromagnetic system, the susceptibility presents a maximum at the ordering temperature, T_N . In the paramagnetic state, the variation of $1/\chi(T)$ vs. T well above T_N is again linear.

$T > T_C$, the only possible solution is $M = 0$; the moments are oriented at random and the system is paramagnetic, as it is in the absence of interactions. In this temperature range, the slope of the reciprocal susceptibility versus temperature is equal to $1/C$, as it is in noninteracting systems (**Figure 1(a)**). At $T = T_C$, the susceptibility diverges (it becomes infinite) and below T_C , a 'spontaneous magnetization,' M_s , exists within matter, indicating a certain degree of common alignment of all the moments. Such behavior characterizes ferromagnetic order (**Figure 2(a)**). The spontaneous magnetization, $M_s(T)$, progressively increases as temperature is decreased; at 0 K, it reaches the value $M_s = M_{s,0} (\equiv Nm_0)$ of the magnetization at absolute saturation (**Figure 1(a)**).

Note that the magnetic energy density, associated with the formation of ferromagnetism, may be expressed as

$$E_{\text{FM}} = -\frac{1}{2}\mu_0 M_s H_m = -\frac{1}{2}\mu_0 n M_s^2 \quad [10]$$

Beyond the Molecular Field Model: Evidence for Short-Range Order

The transition from a low-temperature ordered phase to a high-temperature disordered phase is a feature found in many physical systems. In the present case, the disordered phase is the paramagnetic phase and the ordered phase is the ferromagnetic one. First-order phase transitions are characterized by a discontinuity of thermodynamic variables such as the density or the entropy. In general, no such discontinuity exists at a paramagnetic–ferromagnetic transition. Landau has shown that second-order phase transitions are characterized by an abrupt symmetry change. In the paramagnetic phase, the system is invariant upon reversal of the magnetization; in the ferromagnetic phase, it is not invariant upon this reversal. In the vicinity of T_C , the magnetization is predicted to vary as

Figure 2 Schematic representations of various types of magnetic structures: (a) ferromagnetism, (b) antiferromagnetism, (c) ferrimagnetism, (d) helimagnetism, and (e) modulated structure.

$$M_s = \sqrt{\frac{a}{2b}} (T_C - T)^{1/2} \quad [11]$$

Here $1/2$ is the critical exponent of the magnetization within the molecular field model. Experimentally, this critical exponent, denoted β , is found to be less than 0.5 (i.e., $\sim 0.3 - 0.4$). This departure from the molecular-field-predicted value is due to the existence of local fluctuations of the magnetic state. Proper values of the critical exponents are obtained within the renormalization group theory.

Fluctuations cannot be explained within the molecular field model because H_m is proportional to M_s , a macroscopic quantity. Actually, the existence of magnetic fluctuations indicates that the magnetic interactions are short-ranged. The modification of the state for a given moment influences the state of the neighboring moments, but not that of moments which are at large distances. Magnetic disorder may proceed by keeping a certain degree of local order, while allowing the system to become disordered at the macroscopic level. The magnetic energy is reduced whereas the entropy is the same as for the case of homogeneous disorder. Due to short-range order, the experimental value of the Curie temperature is always lower than that predicted by the molecular field model. Close to T_C , the local correlations existing between moments lead to nonlinearity in the temperature dependence of the reciprocal susceptibility. At temperatures far above T_C , the influence of local fluctuations become negligible and the molecular-field-temperature dependence of the reciprocal susceptibility is recovered. The extrapolated intercept with the temperature axis gives the value of the so-called paramagnetic Curie temperature, θ_C , which is higher than T_C (Figure 1).

The local character of the magnetic interactions manifests itself as well in the ordered magnetic state, at low temperatures. The spontaneous magnetization decreases as $T^{3/2}$, more rapidly than predicted by the molecular field model. Specific excitations such as the spinwaves occur, which allow the local alignment of neighboring moments to be better preserved than in the case of random disorder, while allowing global disorder to develop.

Exchange Interactions

In a given ferromagnetic material, the strength of the molecular field may be derived from the value of the Curie temperature, T_C (see relation [9]). In Fe metal, the Curie temperature amounts to 1043 K, and in Co metal, it amounts to 1380 K; $H_m \approx 10^9 \text{ A m}^{-1}$ is deduced.

From magnetostatics, it is known that a magnetic moment, $\mathbf{m}$, is the source of a dipolar magnetic field, H , which, at point P , is expressed as

$$H = \frac{1}{4\pi} \left[3 \frac{(\mathbf{m} \cdot \mathbf{r})\mathbf{r}}{r^5} - \frac{\mathbf{m}}{r^3} \right] \quad [12]$$

where $\mathbf{r}$ is the vector linking point O to point P. For $m \approx 2\mu_B$, which is the order of magnitude of the Fe or Co moment in metals, the corresponding magnetic field is of the order of 10^6 A m^{-1} . This value is ~ 1000 times smaller than the value derived from T_C . Except in rare cases, magnetic order cannot be attributed to dipolar interactions.

As shown by Heisenberg, the interactions at the origin of magnetic order are not magnetic in origin, but result from the repulsive electrostatic interactions existing between electrons. The Hamiltonian describing an ensemble of interacting electrons contains a term, called the exchange term, which results from electron indiscernibility. Magnetism emerges when account is taken of the Pauli exclusion principle. This stipulates that two electrons cannot occupy the same quantum state, defined by both space and spin variables. It imposes full antisymmetry of the wave function representative of the electron ensemble and, as a result, the interaction energy between electrons depends on their respective spin states.

It is often convenient to distinguish two terms in the exchange interactions. The intra-atomic interactions give rise to Hund's rules which govern the formation of atom magnetic moments; the inter-atomic exchange interactions are the source of the coupling between atom moments which allows magnetic order to be understood.

On the Connection between Exchange Interactions and Molecular Field

Within the Heisenberg theory, the exchange interaction between two spins i and j is generally expressed as

$$e_{ij} = -2J_{ij}S_iS_j \quad [13]$$

where J_{ij} is the exchange integral which represents the strength of the coupling between spins i and j . For an ensemble of N_T spins, the energy density is obtained by summing over all spins:

$$E_{ech} = -\frac{N_T}{V} \sum_{i,j \neq i} J_{ij}S_iS_j \quad [14]$$

where V is the sample volume. Assuming that all atoms are identical, S_i and S_j may be replaced by S . Thus, the magnetic energy density can be written as

$$E_{ech} = -\frac{N_T S}{V} \left(\sum_{j \neq i} J_{ij} \right) S \quad [15]$$

The first part of the right-hand expression in eqn [15] is proportional to the magnetization whereas the second part is proportional to the molecular field. Thus, this expression is equivalent to the molecular field expression of energy (eqn [10]); it also manifests the local character of magnetic interactions.

Magnetic Anisotropy

In ferromagnetic materials, the magnetic moments are aligned along well-defined crystallographic directions. This is the phenomenon of magnetic anisotropy. It is explained by considering that the electrons belonging to the magnetic shells interact with other charges in the environment, which constitute the so-called crystalline electric field (CEF). Due to the orbit asymmetry, the coupling energy depends on the orientation of the orbit within the CEF. A favored orientation of the orbital magnetic moment is intrinsically linked to the favored orientation of the orbit. Since the spin and orbital moments are linked, the total moment aligns along a preferred direction. This is the phenomenon of magnetic anisotropy. The anisotropy is high in rare-earth systems where a large orbital moment exists.

In uniaxial systems, there exists a unique easy direction of magnetization and a hard plane, perpendicular to the unique axis. The anisotropy field is the amplitude of the field applied in the plane and required to force the moments into this plane. In systems of higher symmetry, such as the cubic systems, there exist several easy directions and the anisotropy is weaker in general than in uniaxial systems.

Mechanisms of Magnetic Coupling

Exchange interactions constitute the general source of moment coupling. However, the details of the coupling mechanism may differ strongly from one system to another. In this section, this is illustrated by some representative examples.

Consider 3d electrons in iron, cobalt, nickel, or one of their alloys. The exchange-coupling existing between all electrons sitting on the same site favors a parallel coupling between their spins (Hund's rules). However, the 3d electrons have a certain degree of itinerant character, that is, they have a finite occupancy probability on the atom sites of the environment. An electron, arriving on another site, becomes exchange coupled to the electrons present on this site and again a parallel coupling between spins is favored. Thus, a parallel coupling between the two associated moments is favored. This mechanism explains high-temperature ferromagnetism observed in these systems.

In transition metal oxides, such as MnO , Fe_2O_3 , CoO , or NiO , the fully localized 3d electrons are hybridized with the 2p electrons of oxygen. The d electrons, sitting on two different transition metal atoms but coupled to p electrons on the same oxygen atom, become indirectly coupled together. This mechanism constitutes super exchange. Often, it favors an antiparallel coupling between transition metal spins, that is, the exchange integral J is negative. Nonferromagnetic structures may result.

The 4f electrons of the rare-earth elements occupy an internal electronic shell, which is protected from the environment by more external shells, such as the 5d and 6s ones. The 4f electrons are strongly localized and bear well-defined magnetic moments. No interaction exists with 4f electrons on other sites. However, the 4f electrons are exchange coupled to the 5d and 6s electrons which become polarized. In metallic systems, the 5d, 6s electrons are itinerant. When they travel from one atom to the next, their polarization oscillates with a period which is characteristic of the band structure. Indirect interactions between the localized moments result in the RKKY type. They are the source of an indirect coupling between the 4f moments which is long-ranged and oscillatory.

Nonferromagnetic Types of Magnetic Orders

The possible existence of negative J values explains that diverse types of magnetic orders may exist, in addition to ferromagnetism.

Antiferromagnetism

Consider a system which contains one type of magnetic atoms, all bearing the same magnetic moment, but which may be separated into two groups, A and B, called sublattices. Within the same sublattice, the exchange integrals J_{AA} and J_{BB} (coupling moments) are positive, whereas J_{AB} (the coupling moments belonging to different sublattices) are negative. The magnetic structure is such that all moments within a given sublattice are parallel to each other and antiparallel to the moments within the other sublattice. The resulting global magnetization is zero. Such a moment arrangement characterizes antiferromagnetism (Figure 2(b)). Amongst many other systems, it is found in the transition metal oxides MnO, CoO, or NiO.

Antiferromagnetism may be described within the molecular field model, by decomposing the molecular field into two separate contributions, one from each sublattice. Assuming that the two sublattices are identical, the molecular field may be expressed as

$$H_m = nM_s^{s1} - n'M_s^{s1} \quad [16]$$

where M_s^{s1} is the spontaneous magnetization within each sublattice, n (>0) is the molecular field coefficient representative of the interactions within a given sublattice, and n' (<0) is the molecular field coefficient representative of the interactions between sublattices. The coefficients n and n' are related to the J 's through expressions which are similar to expression [19]. The magnetization of each sublattice is given by expression [3], but with

$$x = \frac{\mu_0 m (nM_s^{s1} - n'M_s^{s1})}{k_B T} \quad [17]$$

One looks for solutions of expressions [3] and [16] simultaneously. Above a critical temperature, T_N , called the Néel temperature, which is the equivalent of the Curie temperature for ferromagnetism, the sublattice magnetization is equal to zero; the slope of the reciprocal susceptibility versus T is the same as found in noninteracting and ferromagnetic systems, equal to $1/C$ (Figure 1b). At $T = T_N$, magnetic order sets in. Below T_N , a nonzero magnetization exists within each sublattice.

In the ordered magnetic state, an applied magnetic field tends to align all moments along itself; it works against inter-sublattice exchange-coupling. As temperature decreases, the ratio of exchange-coupling energy to Zeeman energy increases. Thus, the magnetic susceptibility decreases. Combining this with the usual temperature decrease of the susceptibility in the paramagnetic state, it results that the magnetic susceptibility presents a maximum at T_N . This constitutes a common feature of antiferromagnetic-like structures, in which the global magnetization is zero.

From the point of view of quantum mechanics, Landau noted that the antiferromagnetic configuration described above, termed a Néel state, is not an eigenstate of the corresponding Hamiltonian. The actual ground state is a mixture of the two equivalent Néel states which are obtained by reversing the magnetization in the two sublattices; it is not magnetic. Due to the macroscopic nature of the antiferromagnetic domains, the Néel state is almost indistinguishable from the real ground state. Although not yet experimentally demonstrated, this is not the case in nanosystems.

Ferrimagnetism

Many transition metal oxides incorporate two different magnetic elements. The magnitude of the associated moments differs and a certain magnetization remains even when the moments are coupled antiparallel. Such ferrimagnetic structures (Figure 2(c)) are found in Fe oxides, such as γ -Fe₂O₃ and Fe₃O₄, where Fe moments in different ionic states coexist.

Ferrimagnetism is also found in rare-earth compounds with Fe, Co, or Ni, where an antiparallel coupling between the 3d moments and the rare-earth moments occur.

Helimagnetism and Modulated Structures

In the molecular field description of ferromagnetism, the molecular field is assumed to be a macroscopic entity. However, the local character of the magnetic interactions is established by experimental results which were mentioned above, and it emerges naturally in the Heisenberg description of the exchange interactions.

In the version of the molecular field model developed for the description of antiferromagnetism, the distinction between two different contributions gives to the molecular field a certain local character. In the spirit of a local description, the molecular field on a certain site, i , may be expressed in terms of the sum of the interactions of the moment, m_i , with all other j moments:

$$H_i = \sum_j n_{ij} \langle m_j \rangle T \quad [18]$$

where the n_{ij} 's are molecular field coefficients. By analogy with the analyses described above, the magnetic moment, at temperature T , is given by

$$\langle m_i \rangle_T = m_0 \mathcal{L} \left(\frac{\mu_0 m_0 (H_i)}{k_B T} \right) \quad [19]$$

The high-temperature expansion of this expression is

$$T \langle m_i \rangle_T = C \sum_j n_{ij} \langle m_j \rangle_T \quad [20]$$

with solutions of the type

$$\langle m_i \rangle_T = A \exp(ikR_i) \quad [21]$$

where R_i describes the atom positions and k is a vector. One defines the quantity $\mathcal{J}(k)$ which is the Fourier transform of the exchange interactions:

$$\mathcal{J}(k) = C \sum_j n_{ij} \exp(ik(R_i - R_j)) \quad [22]$$

The critical temperature is given by

$$T_c = \mathcal{J}(k_0) \quad [23]$$

where T_c is the highest temperature for which the set of eqn [20] admits a nonzero solution, and the associated vector k_0 which characterizes the magnetic structure is termed the propagation vector of the structure.

This approach may be illustrated by considering a linear chain of atoms, distant by a , such that the exchange interactions are positive between first neighbors (n_1), negative between second neighbors (n_2), and equal to zero for larger distances. For $n_1 \gg n_2$, the ferromagnetic solution is obtained (for n_1 large and negative, the structure is antiferromagnetic), but this is no more the case for $|n_2| > n_1/4$. When the magnetic moments are confined in the plane perpendicular to the chain by the magnetic anisotropy, a helimagnetic structure is found in which the moments rotate progressively from one to the next, along the chain (Figure 2d). This structure is found in some rare-earth metals, such as terbium or dysprosium. Reciprocally, when the moments are forced to align along the chain axis, a modulated structure occurs in which the amplitude of the moments oscillates periodically (Figure 2e). This occurs in thulium.

Helimagnetic and modulated structures belong to the large class of antiferromagnetic structures, which are characterized by the zero value of the spontaneous magnetization. However, in these two cases, the stable magnetic structure is the result of a compromise between the various interactions involved, and is said to be frustrated. The analysis of frustrated structures has recently been the topic of intense research, both theoretically and experimentally.

Spin Glasses and Other Frustrated Systems

When the magnetic atoms do not form a periodic arrangement, another type of frustrated magnetic arrangement may exist. This is the case in substitutional alloys in which two or more types of atoms are randomly distributed on a given periodic lattice, or in amorphous alloys, obtained by very fast quenching from the melt. Since the magnitude and sign of interactions depend on the distance, it may be expected that the random distribution of atoms leads to a distribution of J values which is centered at 0 such that there are as many positive and negative interactions.

As long as the interactions n_{ij} are evenly distributed from positive to negative, with zero mean value, no stable magnetic order may exist. However, if eqn [20] is squared, one obtains

$$T^2 \langle m_i \rangle^2 = C^2 \left(\sum_j n_{ij} \langle m_j \rangle \right)^2 \quad [24]$$

For a fully disordered system of infinite dimensions, the sum over the terms $n_{ij} \langle m_j \rangle \langle m_j' \rangle$ is zero and eqn [24] can be expressed as

$$T^2 \langle m_i \rangle^2 = C^2 \left(\sum_j n_{ij}^2 \langle m_i \rangle^2 \right) \quad [25]$$

This expression has a critical temperature given by

$$T_c = C \left(\sum_j n_{ij}^2 \right)^{1/2} \quad [26]$$

Below T_c , the system is in a spin-glass state where the moments are randomly oriented. Equation [25] does not apply rigorously to finite-size systems. It has been a long debate to decide whether or not a real phase transition occurs in spin glasses. Experimentally, a peak is observed in the thermal variation of the magnetic susceptibility, but the temperature at which it occurs is found to depend on the time taken for the measurement (Figure 3). Initially, this type of measurement suggested that the spin-glass transition is not a real phase transition. Actually, it is now accepted that the spin-glass transition constitutes a new class of phase transitions in which the first derivative of the magnetic susceptibility versus temperature does not show any anomaly, but derivatives of higher orders do. The frequency dependence of the temperature at which the peak occurs in $\chi(T)$ is related to the fact that the critical slowing down of the magnetic fluctuations extends in spin glasses much farther from the value of the critical temperature than it does in other ordered magnetic systems.

Experimental Studies of Magnetic Structures

The macroscopic magnetic properties of magnetic materials may be derived from the magnitude of the stray field generated by the material magnetization, whether it is spontaneous or induced by the applied field. However, such measurements do not allow the moments of the various constitutive elements to be determined individually. Additionally, in the absence of applied field, antiferromagnetic-like materials do not generate any stray field. For this type of characterization, local probes such as Mössbauer spectroscopy, nuclear magnetic resonance (NMR), or muon-spin rotation (μ SR) may be used. These methods measure the local magnetic field at a particular crystallographic site. Using these methods, the magnetization of individual sublattices in an antiferromagnet can be measured. The μ SR spectroscopy is ideal to investigate a material having small ordered state moment $\sim 0.1 \mu_B$ or a material having a heterogenous structure, such as 'magnetic' and 'nonmagnetic' regions.

Neutron diffraction constitutes an invaluable tool for the study of magnetic arrangements. The neutron bears a small magnetic moment which probes the magnetism existing within matter. Neutron diffraction is the strict analog for the analysis of magnetic structures as X-ray diffraction is for the studies of crystallographic structures. Neutron diffractograms obtained with MnO are shown in Figure 4. In (a), the peak observed at 12° is due to the (1 1 1) reflection; it is characteristic of the face-centered cubic crystallographic structure of this compound. In (b), an additional peak is observed at around 6° . This peak can be indexed as $1/2, 1/2, 1/2$. It is the signature of periodicity doubling. In an antiferromagnetic structure, the alternation of moment orientations leads to periodicity doubling (see scheme in the inset to Figure 4). The diffractograms shown in Figure 4 have a special historical meaning. They constituted, when they were published, the first experimental proof of the existence of antiferromagnetism.

Figure 3 Thermal variation of the susceptibility in a spin glass: a Cu–Mn alloy containing 0.95% of Cu. The measurements of the susceptibility were realized under AC field of different frequencies ($\square$ 1330 Hz, $\circ$ 234 Hz, $\times$ 10.4 Hz, Δ 2.6 Hz). The frequency dependence of the temperature at which the peak occurs in $\chi(T)$ is related to the fact that the critical slowing down of the magnetic fluctuations extends in spin glasses much farther from the value of the critical temperature than it does in other ordered magnetic systems.

Figure 4 Neutron diffractograms obtained with MnO. (a) At 300 K, the material is paramagnetic. The observed (1 1 1) peak near $\theta = 12^\circ$ is characteristic of the cubic crystallographic structure. (b) The additional peak near $\theta = 6^\circ$ observed at 120 K reveal a doubling of the unit cell. It may be associated with the existence of an antiferromagnetic arrangement of the moments (inset).

Today, neutron diffraction has developed to a very sophisticated level; it allows very complex magnetic arrangements, including those found in spin glasses and other disordered systems, to be examined.

X-rays interact with the electrons within matter. Since spin-orbit coupling makes the bridge between electron distribution and magnetism, they probe magnetism as well. Although the magnetic interaction term is very small, magnetic studies using X-rays (X-ray magnetic circular dichroism and X-ray diffraction) have recently developed, thanks to the availability of very intense X-ray sources at synchrotron radiation facilities. A specific feature of X-ray studies is element selectivity, which occurs when the wavelength of the incident radiation corresponds to the characteristic energy of a given absorption edge for some element contained in the material examined. Using magnetic X-ray circular dichroism, the spin and orbital contributions to the magnetization density can be measured separately.

Nomenclature

B	magnetic field (T)
H_m	molecular field ($A\ m^{-1}$)
L	orbital angular momentum ($kg\ m^2\ s^{-1}$)
m_{at}	atomic magnetic moment ($kg\ m^2\ s^{-1}$)
M	magnetization ($A\ m^{-1}$)
S	Stoner enhancement factor (dimensionless)
$\rho(\epsilon)$	density of states ($J^{-1}\ m^{-3}$)

Paramagnetic materials do not order magnetically and have a positive magnetic susceptibility, which means the magnetization is pointing in the same direction as the magnetic field. Inevitably, there is also a diamagnetic susceptibility. The material is classified as paramagnetic if the sum of the two contributions is positive. Nevertheless, the paramagnetic susceptibility can be determined in both kinds of materials. In addition, the paramagnetic susceptibility of magnetically ordered materials (ferro-, ferri-, and anti-ferromagnets) above the transition temperature can be a subject of study.

In the most common paramagnetic materials, the response to an external magnetic field is due to the alignment of atomic magnetic moments under the torque exerted by the field. The potential energy of the moment m_{at} in a field B is

$$V = -m_{at} \cdot B \quad [1]$$

The magnitude of the atomic moment is of the order of the Bohr magneton, $\mu_B = eh/2m_e = 9.27 \times 10^{-24} J T^{-1}$, where e is the electron charge, $h = b/2\pi$ the Planck constant, and m_e the electron mass. Eqn [1] shows that m_{at} tends to align parallel to the magnetic field and the energy gained by alignment in a field of 1T is $\sim 10^{-23}$ J, less than 1% of the thermal energy per degree of freedom, $1/2 k_B T$, at room temperature (k_B is the Boltzmann constant). At ambient temperature, in a regular electromagnet, one should not expect a substantial paramagnetic magnetization. On the other hand, if the moments are free, that is, no interaction hampers their rotation, lowering the temperature can reduce the thermal fluctuations, whereupon the paramagnetic susceptibility will increase. If none of the constituent atoms of a material has a magnetic moment, there can still be a paramagnetic moment, due to moments induced by the magnetic field. The resulting Van Vleck susceptibility is independent of temperature (see below).

The value of the atomic moment depends on the number of electrons and on their angular momentum. The filled shells of the ion cores and of fully ionized species, like O^{2-} or Cu^+ , have zero angular momentum and hence no magnetic moment. The outermost electron shells are often but partially occupied and can carry a magnetic moment. However, in crystalline solids, these shells provide the delocalized Bloch states and contribute to the cohesive energy of the crystal. This requires a considerable overlap of the atomic wave functions on neighboring sites. The corresponding states are severely perturbed and cannot be labeled by the angular momentum quantum numbers ℓ and m_ℓ . In the case of transition metals, lanthanides, and actinides, under certain circumstances, there is a distinction between the outermost s and p states and the more localized states in the d and f shells, which are not fully occupied either. The former are responsible for the cohesion and determine the interatomic distances, while the latter remain localized and can form localized moments. This subtle division of electronic states makes transition and rare-earth metals and their compounds the most important ordered magnetic materials and also the strongest paramagnets.

A given number of d or f electrons will form a total angular momentum in accordance with Hund's rules, which require that (1) the total spin angular momentum S be as large as possible without violating the Pauli principle; (2) the total orbital angular momentum L be as large as possible without violating the Pauli principle and requirement (1); and (3) S and L be aligned antiparallel and form the total angular momentum, $J = |L - S|$, if the shell is less than half filled, and parallel, $J = L + S$, if it is more than half filled.

The hierarchy of the three rules of Hund reflects a hierarchy among the interactions involved. Of these, the exchange interaction, which favors the parallel-spin arrangement, rule (1), is the strongest. The preference for the alignment of orbital moments, rule (2), is dictated by the less important correlation energy, while the spin-orbit coupling, responsible for rule (3), is ineffective in transition metals and quite important in the rare earths. Table 1 shows the ground states following from the three rules for transition-metal ions in the conventional notation $(2S+1)X_J$, where $X = S, P, D$, and F stand for $L = 0, 1, 2$, and 3 , respectively. Also shown are the

effective moments, calculated for the $L - S$ coupled as well as spin-only states, which will be discussed below. **Table 2** gives the corresponding data for the tripositive rare-earth ions (H and I stand for $L = 5$ and 6 , respectively).

If the quantum numbers of the ground state are known, the atomic magnetic moment can be calculated as $m_{\text{at}} = g_I \mu_B J$, where

$$g_I = 1 + \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)}$$

is the Landé g factor.

There is no classical analogy of the above procedure of determining the magnitude of the atomic moments as there should not be one, considering that the Bohr–van Leeuwen theorem precludes orbital magnetism in a classical system. What is often referred to as the classical derivation of the paramagnetic magnetization is the application of classical statistics to the quantum mechanical objects $\mathbf{m}_{\text{at}}$. In the context of classical statistics, the partition function involves the potential energy (eqn [1]), where $\mathbf{m}_{\text{at}} \cdot \mathbf{B} = m_{\text{at}} B \cos \vartheta$, where ϑ is a continuous variable and integration is to be performed over φ and ϑ , the angular coordinates of the vector $\mathbf{m}_{\text{at}}$. In the proper quantum mechanical description, a summation over the possible values of the z component of $\mathbf{m}_{\text{at}}$ is required and the partition function takes the form

$$Z = \left(\sum_{M_J = -J}^J \exp(g_I \mu_B B M_J / k_B T) \right)^{N_{\text{at}}} \quad [2]$$

where N_{at} is the number of atoms or ions. Summation of the geometrical series leads to

$$z = \left(\frac{\sinh(g_I \mu_B B (J + 1/2) / k_B T)}{\sinh(g_I \mu_B B / 2 k_B T)} \right)^{N_{\text{at}}}$$

Deriving the free energy as $F = (-1/k_B T)$ and using $M = (-1/\partial F / \partial B)$, the magnetization is found in the form

$$M = \frac{N_{\text{at}}}{V} g_I \mu_B B_J(g_I \mu_B B)$$

where

$$B_J(x) = \frac{2J+1}{2J} \coth \frac{2J+1}{2J} x - \frac{1}{2J} \coth \frac{1}{2J} x$$

is the Brillouin function. For large values of J , $B_J(x)$ approaches the Langevin function, $L(x) = \coth x - 1/x$ which is the result of the classical treatment outlined above. The susceptibility is found to obey Curie's law,

$$\chi_c = \left(\frac{\partial M}{\partial H} \right)_{H=0} = \frac{N_{\text{at}}}{V} \mu_0 \frac{(g_J \mu_B)^2 J(J+1)}{3K_B T} = \frac{C}{T} \quad [3]$$

where $\mu_0 = 4\pi 10^{-7} \text{TmA}^{-1}$ is the permeability of free space and the Curie constant, C , is implicitly defined by this equation. The Curie law is well obeyed by various salts and other compounds, where the atoms or ions carrying magnetic moments are far enough from each other, so that their interaction, the exchange interaction, is negligible. In these cases the effective magnetic moment, $\mu_{\text{eff}} = g_J \mu_B \sqrt{J(J+1)}$, can be determined from the slope of χ^{-1} versus T plots. In paramagnetic rare-earth materials, the measured μ_{eff} values agree with the Hund's rule values listed in **Table 2**. In most transition-metal oxides and salts, however, the μ_{eff} values calculated from the Hund's rule spin quantum numbers alone are closer to the measured values than the ones involving J , indicating that crystal fields are strong enough to suppress ('quench') the orbital angular momentum. If the exchange interaction between magnetic moments is not negligible, the Curie-Weiss law, $\chi_{\text{CW}} \propto (T - \theta)^{-1}$, often holds. To account for the interaction, whose source was unknown at that time (1907), Weiss has introduced the molecular field H_m , which acts, in addition to the external field H , on each atomic magnetic moment. As H_m is supposed to describe the tendency of atomic moments to point in the same direction, it is assumed to be proportional with the magnetization, $H_m = \lambda M$. Substituting this expression in the expression for the magnetization in the total field,

$$M = \chi_c (H + H_m) = \frac{C}{T} (H + \lambda M)$$

the magnetization can be expressed as $M = \chi_{\text{cw}} H$ with

$$\chi_{\text{cw}} = \frac{\chi_c}{1 - \lambda \chi_c} = \frac{C}{T - \theta} \quad [4]$$

where $\theta = C\lambda$ is the paramagnetic Curie temperature. It is seen that the slope of χ_{cw}^{-1} versus T plots are determined by the effective moment the same way as in the case of the Curie law, but the straight lines representing the measured data do not go through the origin. Deviations from the straight-line behavior may be due to crystal fields.

In most metals, the effect of the crystalline environment is so strong that all couplings imposed by Hund's rules are broken and all but the ion-core electrons are delocalized. In rare-earth materials, the f electrons are localized and form magnetic moments conforming to Hund's rules. In insulators, the d electrons of transition-metal cations remain localized, but the spin-orbit coupling is broken and the orbital angular momentum itself is destroyed. The latter process is called the quenching of angular momentum, not a particularly enlightening term. What it stands for is that, the spherical symmetry around a particular ion being broken by its neighbors in the crystal, the stationary states are no more eigenstates of the angular momentum. Due to the symmetry of the crystalline environment, some degeneracy of the eigenstates may remain. However, if all matrix elements of the three components of the angular momentum, $\hat{L}_x$, $\hat{L}_y$, and $\hat{L}_z$, between the degenerate wave functions vanish, its expectation value vanishes for any linear combination of these functions; the angular momentum is 'quenched.' If that is not the case, the angular momentum may be partially quenched and can be described by an effective angular momentum operator working within the multiplet of the lowest-lying crystal-field level.

Partial or complete quenching of the orbital angular momentum influences the temperature dependence of the paramagnetic susceptibility if the temperature is high enough for the thermal energy $k_B T$ to be comparable to the splitting between the lowest and next-to-lowest crystal-field levels. At temperatures exceeding Δ/k_B , Δ being the total splitting of the ground-state multiplet, the Curie or Curie-Weiss susceptibility is recovered with the effective moment appropriate to that multiplet.

Higher-lying crystal-field states can influence the paramagnetic susceptibility also at very low temperatures, $T \ll \Delta/k_B$. Even though the thermal occupancy of such states is negligible in this limit, the magnetic field will mix them into the ground state via the perturbing Hamiltonian (eqn [1]). Taking account of this perturbation to second order, the corresponding contribution to the susceptibility, the Van Vleck paramagnetic susceptibility, is found to be

$$\chi_{\text{VV}} = \frac{N_{\text{at}}}{V} \mu_0^2 \sum_i \frac{|\int \psi_0^* (\hat{m}_{\text{at}})_z \psi_i d\tau|^2}{\varepsilon_i - \varepsilon_0} \quad [5]$$

independent of temperature. Here ψ_0 , ψ_i are the wave functions and ε_0 , ε_i the energies of the ground state and higher-lying crystal-field states, respectively. The operator representing the atomic magnetic moment is

$$m_{\text{at}} = \mu_B (\hat{L} + 2\hat{S})$$

evidently not proportional to $\hat{J}$. Therefore, $(\hat{m}_{\text{at}})_z$ has nonvanishing matrix elements between the Hund's rule ground state and higher-lying eigenstates of different J values as well. In fact, Van Vleck derived for that case, with ions having small spin-orbit splitting in mind. However, the term 'Van Vleck susceptibility' is used with reference to any temperature-independent contribution to the paramagnetic susceptibility due to the quantum mechanical admixture of higher-lying states.

As mentioned above, crystal fields in insulators constitute a subtle effect, compared to the full delocalization of conduction electrons in metals. The consequence of the latter for the paramagnetic response is indeed drastic. The conduction electrons, instead of following the Curie law (eqn [3]) with $g=2$ and $S=1/2$, contribute only the Pauli paramagnetism, a small, temperature-independent susceptibility,

$$\chi_P = \mu_0 \mu_B^2 \rho(\epsilon_F) \quad [6]$$

where $\rho(\epsilon_F)$ is the density of states per unit volume at the Fermi energy. It is indeed the Pauli principle that suppresses the $1/T$ divergence of χ : most of the electrons are unable to flip their spin, because the opposite-spin state of the same energy is occupied. Only the electrons in states with energies within $k_B T$ from the Fermi energy are given the choice of m_s values implied by eqn [2]. As the density of such electrons is about $K_B T \rho(\epsilon_F)$, the temperature in the denominator of the Curie susceptibility is canceled out and eqn [6] can be seen to follow from eqn [3].

In the alkali metals, $\rho(\epsilon_F) \approx 10^{47} \text{ J}^{-1} \text{ m}^{-3}$ whence from eqn [6] $\chi_P \approx 10^{-5}$, in good agreement with the paramagnetic susceptibility derived from experiment. In transition metals, the density of states is about one order of magnitude larger, but even so, eqn [6] underestimates the paramagnetic susceptibility, which is enhanced by the exchange interaction between the d electrons. Like in the derivation of the Curie-Weiss law, here too the effect of this interaction can be described by the molecular field. The result,

$$x = \frac{\chi_P}{1 - \lambda \chi_P} \quad [7]$$

is formally similar to eqn [4], but it should be noted that it is independent of temperature in this case. Equation [7] gives the exchange-enhanced paramagnetic susceptibility, $S = (1 - \lambda \chi_P)^{-1}$ is the Stoner enhancement factor. Among the transition metals, the largest value of S is observed in palladium, where $S = 10$.

This is an update of P.F. de Châtel, Diamagnetism, Editor(s): Franco Bassani, Gerald L. Liedl, Peter Wyder, Encyclopedia of Condensed Matter Physics, Elsevier, 2005, Pages 414–417, ISBN 9780123694010, <https://doi.org/10.1016/B0-12-369401-9/00518-0>.

Nomenclature

A	vector potential (A)
B	magnetic field (T)
L	canonical angular momentum ($\text{kg m}^2 \text{s}^{-1}$)
M	magnetization (A m^{-1})
$m_e r \times v$	kinetic angular momentum (of electron) ($\text{kg m}^2 \text{s}^{-1}$)
$m_e v$	kinetic momentum (of electron) (kg m s^{-1})
p	canonical momentum (kg m s^{-1})

Diamagnetic materials do not order magnetically and have a negative susceptibility, which means the magnetization is pointing opposite to the magnetic field. Possibly, there is also a paramagnetic susceptibility. The material is classified as diamagnetic if the sum of the two contributions is negative. Nevertheless, the diamagnetic susceptibility can be determined in both kinds of materials.

Diamagnetism is a very small effect, but all the more puzzling. It entails a response of all known materials to an external magnetic field, which manifests itself in a magnetization opposing that field. It appears thus that the magnetic field generates a magnetic dipole, whose orientation is most unfavorable, being at a maximum of the potential energy as a function of the angle between the magnetic field and the magnetization,

$$E = -\mathbf{B} \cdot \mathbf{M} = BM > 0$$

There is no simple, intuitive explanation for this paradox. This is not surprising though, considering that our intuition is mostly based on classical physics. The celebrated Bohr–van Leeuwen theorem states that the classical free energy of a system of charged particles moving in a magnetic field is independent of the field. Since the magnetization is proportional to the derivative of the free energy with respect to the field,

$$\mathbf{M} = \frac{1}{V} \frac{\partial F}{\partial \mathbf{B}} \quad [1]$$

this theorem implies that classical physics, in this case classical mechanics combined with classical statistics, cannot account for any field-induced magnetization, be it paramagnetic (aligned along the field) or diamagnetic (opposing). In the case of diamagnetic metals, whose charge carriers behave like free electrons, this conclusion contradicts what one would expect from electrodynamics. Charged classical free particles exposed to a magnetic field move in circles. Lenz's law of induction requires that the current loops represented by the orbiting electrons produce a magnetization opposed to the field which induces the currents; this should result in a diamagnetic response. It is no wonder that Niels Bohr was fascinated by this paradox. His main interest was the stability of atomic orbitals, which also contradicts classical expectation. He has formulated the rule of angular-momentum quantization, which, imposed on the classical treatment, accounted for the observed stable orbitals. As it will be shown below, the same rule, applied in the presence of a magnetic field, gives the correct answer for the diamagnetism of free atoms. The diamagnetism of free electrons cannot be understood in this semiclassical way, here a fully quantum mechanical treatment is needed.

The formal proof of the Bohr–van Leeuwen theorem is rather simple, but conceals the clue to its counterintuitive implication. Indeed, if one writes the free energy, $F = -k_B T \ln Z$, of a system of N identical particles (taking electrons of mass m_e and charge $-e$), the partition function has the form

$$Z = \prod_{i=1}^N \int \cdots \int d\mathbf{r}_i d\mathbf{p}_i \exp(-H(\{\mathbf{r}_i\}, \{\mathbf{p}_i\})/k_B T) \quad [2]$$

where H is the Hamiltonian, a function of all position vectors $\mathbf{r}_i$ and canonical momenta $\mathbf{p}_i$. The latter are written as

$$\mathbf{p}_i = m_e \mathbf{v}_i - e\mathbf{A}(\mathbf{r}_i)$$

where $\mathbf{A}$ is the vector potential describing the magnetic field, which enters the Hamiltonian via the kinetic energy,

$$E_{\text{kin}} = \frac{1}{2} m_e v_i^2 = \frac{1}{2m_e} [\mathbf{p}_i + e\mathbf{A}(\mathbf{r}_i)]^2$$

To prove the independence of Z from A , one changes the integration variables $\mathbf{p}_i$ to $\mathbf{p}'_i = \mathbf{p}_i + A(\mathbf{r}_i)$ and realizes that this will not change the result of integration, because the shift of the limits of integration, $\pm\infty$, has no effect. The vector potential thus being eliminated from eqn [2], the partition function must be independent of the magnetic field.

To understand the implications of this freedom to shift parameters, it is instructive to carry out the differentiation in eqn [1] for the simple case of a system of N_a identical atoms. If the electron–electron interaction is treated in the mean-field approximation, the N electrons localized on the same atom are described by the Hamiltonian

$$H = \sum_{i=1}^N H^{(1)}(\mathbf{r}_i, \mathbf{p}_i)$$

with

$$H^{(1)}(\mathbf{r}, \mathbf{p}) = V(r) + [\mathbf{p} + e\mathbf{A}(\mathbf{r})]^2 / 2m_e \quad [3]$$

where $V(r)$ is the potential consisting of the potential of the nucleus and of the “other” $N - 1$ electrons, the latter contribution being spherically averaged (central-field approximation). The partition function (eqn [2]) becomes then the product of N identical integrals,

$$Z = \left\{ \int \int d\mathbf{r} d\mathbf{p} \exp(-H^{(1)}(\mathbf{r}, \mathbf{p})/k_B T) \right\}^N = \{Z^{(1)}\}^N$$

and, consequently, the free energy is a sum of N identical terms, $F = -k_B T N \ln Z^{(1)}$. Choosing the gauge

$$\mathbf{A} = -\frac{1}{2}(\mathbf{r} \times \mathbf{B}) \quad [4]$$

one obtains

$$\mathbf{M} = -\frac{N_a}{V} \frac{\partial F}{\partial \mathbf{B}} = -\frac{N_a}{V} \frac{eN}{2m_e} \int \int d\mathbf{r} d\mathbf{p} \mathbf{r} \times [\mathbf{p} - \frac{e}{2}(\mathbf{r} \times \mathbf{B})] \times \frac{\exp(-H^{(1)}(\mathbf{r}, \mathbf{p})/k_B T)}{Z^{(1)}} \quad [5]$$

where N_a is the number of atoms. The result is seen to be proportional to the thermal average of the kinetic angular momentum, $\mathbf{r} \times m_e \mathbf{v}$. This is not unexpected, because currents, the sources of magnetization, are related to the velocity, not the canonical momentum $\mathbf{p}$, of the charge carriers. The same holds for the kinetic energy in the Hamiltonian [3], which appears in the statistical weight factor $\exp(-H^{(1)}/k_B T)$.

Consider now two points in the phase space of a single electron, which are given by the same position vector $\mathbf{r}$ and opposite velocities,

$$\begin{aligned} \mathbf{r}_1 &= \mathbf{r}_2 = \mathbf{r} \\ \mathbf{p}_1 - \frac{e}{2}(\mathbf{r}_1 \times \mathbf{B}(\mathbf{r}_1)) &= -(\mathbf{p}_2 - \frac{e}{2}(\mathbf{r}_2 \times \mathbf{B}(\mathbf{r}_2))) \end{aligned}$$

The statistical weight factors associated with these two points are identical, whereas the kinetic angular momenta have opposite signs and the same magnitude. Therefore, the sum of their contributions to the integral will vanish. The cancelation would have been more obvious, if $\mathbf{p}$ was shifted to $\mathbf{p}' = \mathbf{p} + (e/2)(\mathbf{r} \times \mathbf{B}(\mathbf{r}))$. In that case, the integrand would have become an odd function of $\mathbf{p}'$ resulting obviously in a vanishing $\mathbf{M}$. Again, the freedom to shift the canonical momentum at a given value of $\mathbf{r}$, which amounts to shifting the canonical angular momentum $\mathbf{L} = (\mathbf{r} \times \mathbf{p})$, turns out to be important in the derivation. As classical mechanics puts no constraints on $\mathbf{L}$ and, according to the ergodic theorem underlying classical statistics, a system will visit all possible states of different values of $\mathbf{L}$, it is understandable that $\mathbf{M}$ has to vanish on average.

These considerations suggest that the classical realm need not be left altogether. It may suffice to impose some constraints on the angular momentum, in the spirit of the Bohr model of atoms, to get sensible results for the magnetization. As a uniform magnetic field along the z -axis, $\mathbf{B} = (0, 0, B)$, leaves all rotations around the z -axis as symmetry operations, it is postulated that L_z be limited to the values $m\hbar$, $m = \pm 1, \pm 2, \pm 3, \dots$. To impose this condition, each integral over the entire six-dimensional $(\mathbf{r}, \mathbf{p})$ phase space must be replaced by a sum of integrals, each over a subspace P_m containing only $(\mathbf{r}, \mathbf{p})$ points, for which $(\mathbf{r} \times \mathbf{p})_z = m\hbar$. In particular,

$$Z^{(1)} = \sum_m \int \int_{P_m} d\mathbf{r} d\mathbf{p} \exp(-H^{(1)}(\mathbf{r}, \mathbf{p})/k_B T) = \sum_m Z_m^{(1)}$$

By the definition of the subspace P_m

$$\int \int_{P_m} d\mathbf{r} d\mathbf{p} (\mathbf{r} \times \mathbf{p})_z \exp(-H^{(1)}(\mathbf{r}, \mathbf{p})/k_B T) = m\hbar Z_m^{(1)}$$

so that eqn [5] can be written as

$$M_z = -\frac{N_a}{V} \sum_m \left\{ \frac{eN}{2m_e} \frac{Z_m^{(1)}}{Z^{(1)}} \hbar m + \frac{e^2 N}{4m_e} \langle \rho^2 \rangle_m^{\text{th}} B \right\}$$

where $NZ_m^{(1)}/Z^{(1)} = p_m$ is the thermal occupation probability of the $L_z = m\hbar$ orbit. Introducing the Bohr magneton, $\mu_B = e\hbar/2m_e$, the first term takes the form $p_m m \mu_B$, which can be recognized as the paramagnetic contribution to the magnetization. In the second term, which makes evidently a negative, diamagnetic contribution to the magnetization, $\langle \rho^2 \rangle_m^{\text{th}} = \int \int_{p_m} dr dp \rho^2 \exp(-H^{(1)}(r, p)/k_B T)/Z^{(1)}$ is the thermal average of ρ^2 for the same orbit m . Here, it is assumed that the r vector is in the $z = 0$ plane and $|r| = \rho$, constant. It then follows that

$$M_{\text{dia}} = -\frac{N_a}{V} \frac{e^2}{4m_e} \sum_m \langle \rho^2 \rangle_m^{\text{th}} B$$

In practice, no thermal excitation out of the ground state will occur and $N\langle \rho^2 \rangle_m^{\text{th}}$ can be replaced by the average of the squared radii of occupied orbits. Clearly, at this stage the simple Bohr model fails. It would be a tortuous extension to introduce the principal quantum number n on the basis of the Bohr–Sommerfeld model and the angular momentum quantum number ℓ on an *ad hoc* basis. Even so, only for $T = 0$ would the introduction of the Pauli principle suffice to give the correct result. For $T > 0$, Fermi–Dirac statistics should be applied, which is a further step away from classical physics. In a proper quantum mechanical treatment, $\langle r_2 \rangle$ enters, instead of $\langle \rho^2 \rangle^{\text{th}}$ where $\langle \dots \rangle$ stands for the expectation value and the factor $2/3$ accounts for the difference between the expectation values of $r^2 = x^2 + y^2 + z^2$ and $\rho^2 = x^2 + y^2$. The diamagnetic susceptibility is thus

$$\chi_{\text{dia}}^{(\text{Langevin})} = \frac{M_{\text{dia}}}{H} = -\frac{N_a}{V} \frac{\mu_0 e^2}{6m_e} \sum_j \langle r_j^2 \rangle \quad [6]$$

where the summation is over the occupied orbits j on each atom. Langevin's result for atomic diamagnetism was brought to this form by Pauli.

It is remarkable that Planck's constant does not appear in the expression for the diamagnetic susceptibility, whereas the importance of angular-momentum quantization in its derivation is obvious. Also, eqn [6] is an appealing result, as it enables a seemingly classical interpretation in terms of currents i_j , induced on each orbit j . Such currents will generate magnetic moments $m_j = i_j \alpha_j \propto \langle r_j^2 \rangle$, where α_j is the area enclosed by the orbit j . The sign of the moments (opposite to $\mathbf{B}$) can be understood in terms of Lenz's law and their magnitudes can be derived from Faraday's law of induction. This derivation, however, invokes well-defined orbits, which are modeled by tiny current loops. Bohr has grafted such orbits onto the classical treatment of particles moving in a potential proportional to r^{-1} and postulated the quantization of angular momentum. Remarkably, this supplement to the classical description was sufficient to understand quantized energy levels and line spectra, as well as diamagnetism.

The validity of eqn [6] turns out to extend beyond the case of atomic orbits. Most notably, it is applicable to ring-shaped molecules, whose structure offers extended orbits. The diamagnetic susceptibility of substances containing such molecules is known to be anisotropic, being larger in magnitude if the magnetic field is applied perpendicular to the plane of the ring-shaped molecules,

$$|\chi_{\text{dia}}^{\perp}| > |\chi_{\text{dia}}^{\parallel}|$$

The interpretation of this phenomenon in terms of "ring currents" goes beyond the qualitative argument that the induced magnetic moments are maximized in the perpendicular configuration. For benzene, C_6H_6 , the anisotropic susceptibility

$$\chi^{\text{an}} = \chi_{\text{dia}}^{\perp} - \chi_{\text{dia}}^{\parallel}$$

is found to be close to what eqn [6] gives. The summation in eqn [6] is to be taken over the six carbon p electrons, which, not being localized in sp^2 hybrid states, are free to move around the molecule:

$$\chi_{\text{benzene}}^{\text{an}} = -6 \frac{A}{V_m} \frac{\mu_0 e^2}{4m_e} \rho^2 = -\frac{A}{V_m} \frac{i_r}{H} \alpha_{\text{hex}} \quad [7]$$

Here, A/V_m is the density of molecules, A being Avogadro's number and $V_m = 89 \times 10^{-6} \text{ m}^3$ the molar volume of benzene, $\rho = 0.139 \text{ nm}$ is the distance from the axis of the molecule to the carbon nuclei and i_r is the total ring current carried by the six delocalized electrons. Pauling has shown in 1936 that the ratio of the anisotropic susceptibility of other, more complicated aromatic hydrocarbons to that of benzene is correctly given by a simple model of conducting networks, assuming that the "resistance" of a carbon–carbon bond is the same in all such molecules. The ultimate success of this model is the correct estimation of the anisotropic susceptibility of graphite. The crystal structure of graphite consists of honeycomb-like layers built of benzene-like units. Assuming that in each hexagonal unit a ring current is induced of the same magnitude as in benzene, one finds that the current of neighboring unit cells cancel and the current density inside the material vanishes. However, the outermost hexagons have two sides with uncompensated currents i_r flowing in a zigzag pattern at 30° from the orientation of the surface. The resulting surface current density is $j_s = i_r \cos 30^\circ / d$, where $d = 0.335 \text{ nm}$ is the interlayer distance in graphite. The surface current density j_s generates a magnetization $M_{\text{graphite}} = -j_s = -i_r \sqrt{3}/2d$ inside the sample. This is to be compared with $M_{\text{benzene}} = -(A/V_m) i_r \alpha_{\text{hex}}$ (cf. eqn [7]), leading to

$$\frac{\chi_{\text{graphite}}^{\text{an}}}{\chi_{\text{benzene}}^{\text{an}}} = \frac{\sqrt{3}V_{\text{m}}}{2A\alpha_{\text{hex}}d} = 7.6 \quad [8]$$

which is close enough to the experimental value of 6.9, considering the simplicity of the model.

Semiclassical and empirical schemes like the ones used above for free atoms and aromatic compounds, respectively, cannot be applied to the diamagnetic response of conduction electrons in metals. Even the simplest model, the free-electron gas, has been a major challenge, until Landau gave his derivation of what has come to be called Landau diamagnetism. In fact, in most textbooks the Bohr–van Leeuwen theorem is only mentioned in this context, even though its validity is not violated by the presence of atomic or molecular potentials.

The Schrödinger equation was four years old, when Landau (who was twenty-one at the time) solved it for free electrons in the uniform magnetic field (eqn [6]). Instead of the symmetric gauge (eqn [4]), he has chosen

$$\mathbf{A} = (0, xB, 0) \quad [9]$$

which enabled the separation of variables. The resulting differential equation in x was found to be identical with the Schrödinger equation of a harmonic oscillator with a force constant e^2B^2/m_e , while the ones in y and z were satisfied by plane-wave solutions. The latter is reasonable for the z dependence, considering that the Lorentz force is perpendicular to $\mathbf{B}$, so that the motion along the z axis is free. The density of the eigenstates described by $e^{ik_z z}$ is that of a one-dimensional electron gas,

$$\rho(\varepsilon) = \frac{2eB}{h^2} \sqrt{2m_e \varepsilon} \quad [10]$$

The motion in the (x, y) plane gives a discrete spectrum, with highly degenerate states at the energies

$$\varepsilon_n = \left(n + \frac{1}{2}\right) \frac{\hbar e}{m_e} B \quad [11]$$

the Landau levels, which correspond to the stationary states of the harmonic oscillator. The resulting total density of states has a spiked structure. A singular contribution of the form [10] begins at each level [11]. These $\rho(\varepsilon - \varepsilon_n)$ contributions stand for the motion in the z direction while the motion in the (x, y) plane corresponds to the n th level of the harmonic oscillator. As to the x - and y -dependence of the wave functions, they are not suggestive of the circular motion resulting from the classical equations of motion for a charged particle subjected to a uniform magnetic field. This may seem to be due to the choice of the asymmetric gauge [9]. However, it is hardly surprising that the classical motion is not implied by the calculation of an effect, which does not occur at all in the classical theory.

The maxima in the density of states at energies separated by $\hbar e B/m_e$ result in a total energy, which is a periodic function of $1/B$. Through eqn [1], a similar periodicity arises in the magnetization, which is the signature of the de Haas–van Alphen effect. In the low-field limit, the same B -dependent total-energy expression yields the diamagnetic susceptibility

$$\chi_{\text{dia}}^{(\text{Landau})} = -\frac{n\mu_{\text{B}}^2}{\varepsilon_{\text{F}}}$$

where n is the electron density and ε_{F} is the Fermi energy. This is seen to be $-1/3$ times the Pauli paramagnetic susceptibility, a relationship, which cannot be expected to be valid for metals in general, but seems to hold for the so-called “simple” metals, for which the nearly free-electron approximation works.

Introduction

As far as isolated atoms are concerned, only two different magnetic behaviors exist: diamagnetism and paramagnetism. The latter property is only present if the considered atoms possess a nonzero permanent magnetic dipole, and is responsible for the weak attractive force experienced by a paramagnetic substance in an applied magnetic field. However, the most interesting magnetic properties of condensed matter arise when the interaction between the individual elementary moments of each atom is considered. In particular, ferromagnetism concerns the situation where the moments have the tendency to align, one parallel to another, even in the absence of any external magnetic field, thus leading to the possibility of obtaining very large values of the magnetization with very little values of the applied magnetic field (spontaneous magnetization). Only a few elements in the periodic table (Fe, Co, Ni, Gd, Dy, and Tb) order ferromagnetically, but an extremely large number of compounds and alloys do. From the practical point of view, apart from their high values of the magnetic susceptibility and relative permeability, one of the most interesting properties of ferromagnetic compounds is the possibility of retaining a large amount of the induced magnetization when the external field is completely removed. This makes it possible to develop devices such as permanent magnets (i.e., magnetized bodies which produce a constant magnetic field in a given volume of space without the need to continuously supply electrical or chemical energy), memory storage devices, magnetic circuits, etc.

The Molecular Field Approach to Ferromagnetism

At the beginning of the twentieth century, Pierre Weiss interpreted the tendency of ferromagnets to spontaneous magnetization by introducing a “molecular field” responsible for the ordering of the elementary magnetic moments, and he assumed that this field is linearly proportional to the bulk magnetization (total magnetic moment per volume unit). It may be recalled that the magnetization of a set of identical noninteracting ions, each having total angular momentum J , in a magnetic field H can be expressed as

$$M = n g \mu_B J B_J \left(\frac{g \mu_B J H}{k_B T} \right) \quad [1]$$

where g is the Landé factor and

$$B_J(x) = \frac{2J+1}{2J} \coth\left(\frac{2J+1}{2J}x\right) - \frac{1}{2J} \coth\left(\frac{x}{2J}\right) \quad [2]$$

is the Brillouin function; the magnetization of a ferromagnet can then be obtained by substituting in eqn [1] the applied magnetic field H with $H + \lambda M$, leading to the implicit equation

$$\frac{M}{ng\mu_B J} = B_J\left(\frac{g\mu_B J}{k_B T} H + \frac{g\mu_B J}{k_B T} \lambda M\right) \quad [3]$$

In order to investigate the possibility of spontaneous magnetization, the $H = 0$ case is considered; eqn [3] can be rewritten as

$$m = tx = B_J(x) \quad [4]$$

with

$$x = \frac{g\mu_B J \lambda M}{k_B T}; \quad t = \frac{k_B T}{n\lambda(g\mu_B J)^2} \quad [5]$$

A graphical solution of eqn [4] is given in Figure 1; if $t \geq t_C = (J+1)/3J$, only the trivial solution $x = 0$ is present, while otherwise there is also a possible solution with $x \neq 0$. This means that there exists a critical temperature T_C (Curie temperature), below which a ferromagnetic compound can have a nonzero magnetization in the absence of an applied magnetic field. The Curie temperature and saturation magnetization for several ferromagnetic elements are listed in Table 1. It is worth noting that eqn [4] can be expressed in terms of J , $m = M(T)/M(0)$ and $t = (J+1)/(3J) T/T_C$ only. In the classical limit ($J \rightarrow \infty$), $B_J(x)$ is substituted by the Langevin function $\coth x - 1/x$, and the function $m(t)$ is the same for all ferromagnetic materials; the latter statement is often referred to as the law of corresponding states.

Figure 2 shows the temperature dependence of the magnetization measured for nickel (Ni), together with the curve derived from eqn [4] considering a pure-spin moment $J = S = 1/2$. The overall agreement is fairly good, and can be further improved by the use of more accurate models (the low-temperature decrease due to spin waves and the critical behavior near T_C are shown as dashed lines for comparison).

Above T_C , the sample is in a paramagnetic phase (disordered moments), and its magnetic susceptibility can be calculated by noting that $B_J(x) \simeq (J+1)x/(3J)$ for small values of x , leading to

Figure 1 Graphical solution of eqn [4] (see text for details).

Table 1 Curie temperature, saturation magnetization at room-temperature, and magnetic moment per formula unit (at 0 K) of ferromagnetic elements

Figure 2 Experimental (diamonds) and calculated (lines) value of $m = M(T)/M(0)$ vs. $t = T/T_C$ for nickel ($J = S = 1/2$). Experimental data are taken from Weiss P and Forrer R (1926) Aimantation et phenomene magnetocalorique du nickel. *Ann. Phys.* 5: 153. The full black line is calculated by means of eqn [4]; dashed lines take into account the spin-wave excitations at low T and the critical behavior near the Curie point.

$$\chi \equiv \frac{M}{H} = \frac{C}{T - \lambda C} \quad [6]$$

where C can be identified with the paramagnetic Curie constant ($\chi = C/T$ if no ferromagnetic order exists, i.e., $\lambda = 0$) and $T_C = \lambda C$. This very simple model gives a fairly accurate description of the experimental magnetic susceptibilities of ferromagnetic compounds at high temperatures.

It must be noted that λM can be as large as several times the maximum magnetic field which can be produced in a standard laboratory, and is about four orders of magnitude larger than the dipolar interaction due to the other magnetic ions in the crystal. The physical origin of this huge molecular field was not clear until the development of quantum mechanics made it possible to point out the role of the exchange interaction (a purely quantum effect and a direct consequence of Pauli's principle) in determining the magnetic spin alignment. The exchange interactions between a collection of N spins can be described by the Heisenberg–Dirac Hamiltonian, which has the form

$$H_{H-D} = - \sum_{i,j} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \quad [7]$$

where the sign of the exchange constants J_{ij} depends on whether the two spins labeled i and j are coupled ferromagnetically (positive) or antiferromagnetically (negative), and the sum usually involves only the z nearest neighbors since the interaction strength drops very rapidly as the distance increases. In the presence of an applied magnetic field H , the Zeeman term

$$H_Z = -2\mu_B \sum_i \mathbf{H} \cdot \mathbf{S}_i \quad [8]$$

must also be considered (a gyromagnetic factor of 2 was taken, in the hypothesis that pure spin moments are being dealt with). The molecular field approximation consists in reducing the N -body Hamiltonian $H_{H-D} + H_Z$ to N one-body Hamiltonians H_i , by replacing all the spin operators except $\mathbf{S}_i$ with their average values:

$$H_i = -\mathbf{S}_i \cdot \left[\sum_j J_{ij} \langle \mathbf{S}_j \rangle + 2\mu_B \mathbf{H} \right] \quad [9]$$

The case now considered is that of a ferromagnetic body, with all the relevant exchange constants $J_{ij} = J > 0$ for simplicity. Since

$$\mathbf{M} = 2\mu_B \sum_i \langle \mathbf{S}_i \rangle \quad [10]$$

is the total magnetization of the sample, eqn [9] can be rewritten as

$$H_i = -2\mu_B \mathbf{S}_i \cdot [\mathbf{H} + \lambda \mathbf{M}] \quad [11]$$

with

$$\lambda = \frac{zJ}{4\mu_B^2 N} \quad [12]$$

Equation [11] immediately shows that the mean-field analysis based on the Heisenberg–Dirac exchange Hamiltonian provides an *a posteriori* justification to Weiss' molecular-field hypothesis; as one might expect, the accuracy of this approximation is higher when z and J are larger, since in this case the role of the fluctuations $\mathbf{S}_i - \langle \mathbf{S}_i \rangle$ is practically negligible and the substitutions made in eqns [7] and [8] are well-grounded.

One word of caution is required before the end of this section. The existing theories of magnetism may roughly be divided into two groups, dealing respectively with localized and itinerant magnetic moments. The Heisenberg approach which was mentioned before belongs to the former; to give a meaning to eqn [7], it must be explicitly assumed that each ion in the crystal carries on it a well-defined magnetic moment S_i due to the electrons which are bound to it. Although this approach is very useful when dealing with certain substances and alloys and for studying critical magnetic behaviors, its validity for metals is questionable due to the presence of conduction electrons, not tied to a specific ion but belonging to the whole crystal. On the other hand, band models considering the role of itinerant electrons have managed to solve several flaws of localized theories, such as the noninteger values of the magnetic moment per atom experimentally measured in most ferromagnets (Table 1), which could not be explained within a localized-moment framework.

Magnetostatic Energy and Demagnetizing Field

One may consider a sample of a magnetic substance, composed of n magnetic atoms per unit volume, each carrying an elementary moment μ , and imagine applying a magnetic field which is strong enough to align all these dipoles along the same directions. As a result of this process, the sample will display a saturation magnetization

$$M_S = n|\mu| \quad [13]$$

(it may be recalled that the magnetization is defined as the total magnetic moment per volume unit).

The energy required to obtain this configuration is

$$E = -\mu_0 \int \mathbf{H} \cdot d\mathbf{M} \quad [14]$$

where $\mathbf{H}$ indicates the magnetic field and $\mathbf{M}$ is the magnetization vector. In the absence of dissipative processes, an equivalent amount of magnetic potential energy is stored within the sample.

In turn, any magnetized body produces a magnetic field in its surrounding space, as one can immediately witness by means of a compass needle. In close analogy with the charge polarization of a dielectric material, one can describe this field as being generated by “free” magnetic poles (i.e., positive poles not neutralized by the presence of a negative pole in their immediate neighborhood and vice versa) on the surface; in addition to this, the presence of a magnetic field generated by an external source is usually considered. Outside the sample, the magnetic induction $\mathbf{B}$ and the magnetic field $\mathbf{H}$ are always proportional (as $\mathbf{B} = \mu_0[\mathbf{H} + \mathbf{M}]$ and $\mathbf{M} = 0$) and their flux lines are oriented from the north (N) to the south (S) poles. On the other hand, the total magnetic field $\mathbf{H}_{\text{int}}$ inside the sample is found by summing the external field, which is parallel to the magnetization, and the contribution from the free poles, which is antiparallel to it (in fact, the flux lines of $\mathbf{H}$ always begin on N poles and end on S poles except when the magnetic field is due to electric currents, in which case they are closed and continuous). The free-poles contribution is also called demagnetizing field, and can be represented as

$$\mathbf{H}_d = -\underline{N}_d \cdot \mathbf{M} \quad [15]$$

where $\underline{N}_d$ is, in general, a second-order tensor whose components depend on the geometry of the studied system; in some particular cases and/or for special directions of the magnetic field, $\mathbf{M}$ and $\mathbf{H}$ are collinear, and one can write a simpler relation where N_d is a dimensionless number called demagnetizing factor. For example, a homogeneous spherical sample (Figure 3) has $N_d = 4\pi/3$, hence

$$\mathbf{H}_d = -\frac{4\pi}{3} \mathbf{M} \quad [16]$$

Demagnetizing factors for samples of various geometries and for different field directions can be found in specialized textbooks.

Magnetic Anisotropy

Another contribution to the energy balance, that is, magnetic anisotropy, will be dealt with now. While the meaning of such a locution is quite simple (the magnetic behavior of a material depends on the direction), it is not easy to understand the physical reasons behind its very existence. In fact, magnetic anisotropy may be produced by several different mechanisms, which include (but are not limited to) magnetocrystalline (or crystal-field) anisotropy, shape anisotropy, stress anisotropy, annealing in a magnetic field, etc. For the sake of simplicity, the considerations made in the following will be referred to a uniformly magnetized single-crystal sample.

From a phenomenological point of view, the effect of magnetic anisotropy may be taken into account by adding to the energy balance an extra term E_A (anisotropy energy), which depends on the relative orientation of the magnetization vector with respect to the crystallographic axes. As shown by the Russian physicist Akulov, the free anisotropy energy per unit volume can always be expressed by an infinite series

Figure 3 Magnetic field generated inside and outside a uniformly magnetized sphere. The magnetization vector $\mathbf{M}$ is directed from the S to the N pole; the resulting demagnetizing field (inside the sphere) is antiparallel to $\mathbf{M}$.

$$\begin{aligned}
 E_A &= \sum_{n=1}^{+\infty} \left(\sum_{i_1=1}^3 \sum_{i_2=1}^3 \cdots \sum_{i_n=1}^3 c_{i_1, i_2, \dots, i_n} \alpha_{i_1} \alpha_{i_2} \cdots \alpha_{i_n} \right) \\
 &= \sum_{i=1}^3 c_i \alpha_i + \sum_{i=1}^3 \sum_{j=1}^3 c_{ij} \alpha_i \alpha_j + \sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 c_{ijk} \alpha_i \alpha_j \alpha_k + \sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 \sum_{l=1}^3 c_{ijkl} \alpha_i \alpha_j \alpha_k \alpha_l + \cdots
 \end{aligned} \tag{17}$$

where α_1 , α_2 , and α_3 are the direction cosines of the magnetization vector with respect to the Cartesian axes x , y , and z , and several coefficients may equal zero for symmetry reasons; for example, all the terms of the sum with odd n vanish if eqn [17] is invariant under inversion of the magnetization. In most relevant cases, eqn [17] can be rewritten as

$$E_A = \sum_{n=1}^{+\infty} K_n A_n(\alpha_1, \alpha_2, \alpha_3) \tag{18}$$

for example, a ferromagnetic crystal with cubic lattice symmetry has $A_0(\alpha_1, \alpha_2, \alpha_3) = 1$; $A_1(\alpha_1, \alpha_2, \alpha_3) = \alpha_1^2 \alpha_2^2 + \alpha_1^2 \alpha_3^2 + \alpha_2^2 \alpha_3^2$; $A_2(\alpha_1, \alpha_2, \alpha_3) = \alpha_1^2 \alpha_2^2 \alpha_3^2$; etc. The coefficients K_n , named anisotropy constants, can be determined by magnetization measurements; a knowledge of a reliable set of anisotropy constants for a given sample can lead to a direct phenomenological interpretation of the magnetic processes and is useful to make comparisons between different systems.

For lattices with uniaxial symmetry (e.g., cylindrical, hexagonal, and tetragonal), compact expressions for the anisotropy energy can be derived as a function of the polar and azimuthal angles θ and φ , which define, respectively, the angle between the magnetization vector $\mathbf{M}$ and the z -axis (coincident with the symmetry axis), and the angle between the projection of $\mathbf{M}$ on the xy -plane and the x -axis. In this case,

$$E_A = \sum_{n=0}^{+\infty} \sin^{2n} \theta \sum_{0 \leq l < n/m} K_n^{(l)} \cos(lm\varphi) \tag{19}$$

As for the cubic phase, the K_0 term is an isotropic energy shift, and will therefore be dropped in the following. The value of m depends on the particular symmetry, leading to

$$E_A = K_1 \sin^2 \theta + K_2 \sin^4 \theta + K_3 \sin^6 \theta + K'_3 \sin^6 \theta \cos 6\varphi + \cdots \tag{20}$$

($m = 6$) for a hexagonal lattice and

$$E_A = K_1 \sin^2 \theta + K_2 \sin^4 \theta + K'_2 \sin^4 \theta \cos 4\varphi + K_3 \sin^6 \theta + K'_3 \sin^6 \theta \cos 4\varphi + \cdots \tag{21}$$

($m = 4$) for a tetragonal system. For a perfectly cylindrical system ($m \rightarrow \infty$), the anisotropy on the xy -plane vanishes and one is left with

$$E_A = \sum_{n=0}^{+\infty} K_n \sin^{2n} \theta \tag{22}$$

If no applied field is present, the sample magnetization will have the tendency to stay along a direction where the anisotropy energy is lowest; this is called in brief “easy magnetization direction” (EMD). This feature will be discussed in detail later, but it may be immediately inferred that the larger the anisotropy, the larger the magnetic field required to rotate the magnetization direction. Therefore, anisotropy is a key property to take into account when designing or choosing suitable magnetic compounds for particular applications.

In the following section, the most important physical mechanisms giving rise to magnetic anisotropy are discussed in brief.

Magnetocrystalline Anisotropy

Exchange interaction in a ferromagnet can be seen as a spin–spin coupling which aligns the spin moments along the same direction. On the other hand, the orbital moments of any magnetic ion in the lattice preferably align along given crystallographic directions due to the crystal-field potential, which reflects the local crystal symmetry. Magnetocrystalline anisotropy is generated by the spin–orbit interaction, which favors mutual alignment between the spin and orbital moments; if this coupling is relatively strong, as for rare-earths and actinides, moment directions which are farther from the crystallographic easy-axis will have a higher cost in energy. Although several types of anisotropy exist, only magnetocrystalline anisotropy is intrinsic to the material.

In terms of anisotropy constants, subsequent terms of eqn [18] will contain increasing powers of the ratio of the spin–orbit energy to that of the crystal field. As the spin–orbit interaction is weak for 3d metals, the series is generally truncated after the second or fourth order, and only terms in K_1 and K_2 are included. In principle, this is not possible for 4f elements; however, in the case of intermetallic rare-earth–transition-metal alloys, approximate expressions can be found as linear combinations of generalized Brillouin functions, with appropriate coefficients related to the decomposition in terms of spherical harmonics of the crystal-field potential at the rare-earth site. On these grounds, it is usually possible to consider $K_n = 0$ for $n \geq 4$. The typical temperature dependence of anisotropy constants is shown in Figure 4. On changing the temperature, the anisotropy constants of different order can have different relative variations; as a result of this, the EMD of a sample may spontaneously change, giving rise to a spin reorientation transition (SRT) induced by temperature even in the absence of a magnetic field.

Shape Anisotropy

The free poles on the surface of a perfectly spherical and homogeneous sample give rise to a demagnetizing field which is collinear and linearly proportional to the magnetization vector, as described by eqn [16]. In more general terms, however, one must refer to eqn [15] to find the correct value and direction of the demagnetizing field corresponding to a given magnetization vector. The relatively simple case of an elongated rotation ellipsoid with two axes of equal length is considered; for symmetry reasons, one has

$$\begin{aligned} \underline{N}_d &= \begin{pmatrix} N_{\perp} & 0 & 0 \\ 0 & N_{\perp} & 0 \\ 0 & 0 & N_{\parallel} \end{pmatrix} \\ &= \begin{pmatrix} N_{\perp} & 0 & 0 \\ 0 & N_{\perp} & 0 \\ 0 & 0 & N_{\perp} + \Delta N \end{pmatrix} \end{aligned} \quad [23]$$

where $\Delta N = N_{\parallel} - N_{\perp}$. According to eqn [15] and knowing that all homogeneous bodies delimited by second-order surfaces magnetize uniformly, one can write

Figure 4 Typical temperature behavior of anisotropy constants (arbitrary units are used).

$$\mathbf{H}_d = -N_d \mathbf{M} = -N_\perp \mathbf{M} - \Delta N (\mathbf{M} \cdot \hat{\mathbf{z}}) \hat{\mathbf{z}} \quad [24]$$

where $\hat{\mathbf{z}}$ is the unit vector along the direction of the elongated axis of the ellipsoid. The associated energy can be calculated as

$$E = -\mu_0 \int \mathbf{H}_d \cdot d\mathbf{M} = \mu_0 M^2 \left(\frac{N_\perp}{2} + \frac{\Delta N}{2} \cos^2 \theta \right) = \mu_0 M^2 \left(\frac{N_\parallel}{2} - \frac{\Delta N}{2} \sin^2 \theta \right) \quad [25]$$

which corresponds to eqn [22], the only nonzero anisotropy constants being $K_0 = \mu_0 M^2 N_\parallel / 2$ and $K_1 = -\mu_0 M^2 \Delta N / 2$. The extrinsic character of shape anisotropy can be immediately noticed, as the calculated K_1 strongly depends on the shape and bulk magnetization of the sample. While shape anisotropy is usually smaller than crystal-field anisotropy for ferromagnetic rare-earth elements and alloys, they may be of the same order of magnitude for transition metals such as iron and cobalt.

Stress Anisotropy

Applying mechanical stress treatments such as lamination, rolling, or extrusion to a magnetic sample can lead to significant crystal deformations. Stress anisotropy may then be generated due to the magnetoelastic coupling between the lattice and the magnetic moments present in the system (magnetostriction).

Anisotropy Induced by Magnetic Annealing

Heat treatments performed under the Curie temperature of the sample in the presence of an applied magnetic field ("magnetic annealing") may result in the generation of uniaxial anisotropy with respect to the field direction. The induced anisotropy is, in general, rather small, although larger effects may be obtained when a structural transition takes place during the annealing.

Magnetic Domains

As has been mentioned in the introduction, the situation of complete alignment of the elementary magnetic dipoles present in a ferromagnetic substance is energetically favorable due to the exchange interaction. However, it is easy to verify that a piece of iron, taken off the shelves and kept below its Curie temperature, is basically unmagnetized and does not produce any magnetic field. Thermal disorder should obviously not be expected to affect the net magnetization significantly, since the exchange interaction responsible for the alignment of the moments is several orders of magnitude larger than the dipole-dipole interaction in a paramagnet. On the other hand, if one sticks to the molecular-field approach, one must be aware that the solution $M = 0$, $H = 0$ satisfies eqn [3] both above and below T_C .

In order to gain some physical insight on this point, the energy of a magnetized body, under the effect of an external magnetic field $\mathbf{H}$, is considered:

$$E = -\mu_0 \int (\mathbf{H} + \mathbf{H}_d) \cdot d\mathbf{M} \quad [26]$$

In the simple case that the magnetization is uniform all over the sample and that the demagnetizing field can be expressed as $\mathbf{H}_d = -N_d \mathbf{M}$, eqn [26] becomes

$$E = -\mu_0 \mathbf{H} \cdot \int d\mathbf{M} + \mu_0 N_d \int \mathbf{M} \cdot d\mathbf{M} = -\mu_0 \mathbf{H} \cdot \mathbf{M} + \mu_0 N_d \frac{M^2}{2} \quad [27]$$

The first term on the right-hand side is the familiar expression for the Zeeman energy, and can be minimized by aligning the magnetization vector with the external field and maximizing its modulus. The second term is the self-energy of the magnetized body due to the free poles, and can be minimized by minimizing the net magnetization. On the other hand, this term also represents the amount of energy which is stored in the external magnetic field generated by the sample; therefore, if the applied field $\mathbf{H}$ equals zero, it can be inferred that in the lowest energy state, the magnetic field generated by the sample must be as small as possible. From the microscopic point of view, the energy balance results from a competition between exchange coupling (which lowers the total energy if two spins are parallel) and the dipole-dipole interaction (which raises the total energy if two spins are parallel). As a result, the sample is divided in several macroscopic regions, each one having uniform magnetization, called domains. Within a single domain, the spins are parallel to one another; in turn, spins belonging to two different domains can have very different directions (Figure 5) in order to minimize the bulk magnetization.

One may naively expect that the subdivision in domains occurs as in Figure 6a (i.e., all the spins belonging to domains A and B are arranged along the easy-axis direction), and that spins belonging to different neighboring domains are antiparallel to one another. This configuration certainly minimizes the anisotropy energy, but at a large cost of exchange energy for the two antiparallel spins situated at the interface. In general, it is less expensive to have the spins arranged as in Figure 6b; the 180° spin rotation is performed in several different steps within a region between domains A and B, known as "Bloch wall." For the sake of clarity, consider the case of a simple cubic crystal with lattice constant a , with a nearest-neighbor exchange constant J and EMD along $[1\ 0\ 0]$.

Figure 5 Schematic view of the dipole arrangements in (a) a paramagnet (or ferromagnet above T_C), (b) a magnetized (saturated) ferromagnet, and (c) an unmagnetized ferromagnet (divided into domains). While the moments in the paramagnetic phase are disordered at the atomic level, the domain size is macroscopic (even several hundred micrometers).

The energy balance may be estimated by assuming that the rotation is performed within the xz -plane in N equal steps, each of an angle π/N ; then the total exchange energy per unit area of the Bloch wall is

$$E_{\text{ex}} = -J \sum_{l=0}^N \mathbf{S}_l \cdot \mathbf{S}_{l+1} = -J \sum_{l=0}^N S^2 \cos \frac{\pi}{N} = -JS^2 \frac{(N+1)}{a^2} \cos \frac{\pi}{N} \quad [28]$$

while, according to eqn [18] with $\alpha_y = 1$, $\alpha_z = \cos \theta$, and $\alpha_x = \cos(\pi/2 - \theta) = \sin \theta$, the anisotropy energy per area unit is

$$E_A = a \sum_{l=0}^N K_1 \sin^2 \frac{l\pi}{N} \cos^2 \frac{l\pi}{N} = \frac{aK_1}{8} N \quad [29]$$

Figure 6 Schematic view of the dipole arrangements at the boundary between two domains (Bloch wall).

(strictly valid for $N > k$). E_{ex} and E_A are opposite in sign, and the absolute value of both grows with N ; the actual size of the Bloch wall then results from a competition of the two, being smaller when the anisotropy dominates and larger when the exchange interaction dominates. In the large- N limit $E_{\text{ex}} \simeq JS^2\pi^2/(Na^2)$, and minimizing the total energy gives an approximate domain wall width of

$$\ell = Na \simeq 2\pi S \sqrt{\frac{2J}{aK_1}} \quad [30]$$

typically a few hundred lattice constants for iron.

The Magnetization Curve

From the macroscopic point of view, ferromagnets may be considered at a first glance as magnetic materials with extremely large susceptibility and permeability. In practice, as both of them are strongly dependent not only on the temperature, but also on the applied field and on the past history of the sample, they are not very useful parameters and it is quite simple to describe the physical properties of a ferromagnet by means of M versus H (or B versus H , being $B = \mu_0(H + M)$) plots, whose main characteristics will be discussed in the following sections.

The Hysteresis Cycle

When an external magnetic field is applied to a ferromagnetic sample in a demagnetized state in order to bring its resulting magnetization to saturation, one obtains the magnetization curve shown in Figure 7. Two distinct and coexistent processes must be considered in order to understand this (Figure 8): boundary motion and domain rotation. In the former case, those domains which are favorably oriented with respect to the applied field grow in size at the expense of the others, without changing their overall magnetization direction; this process is dominant at low fields. At intermediate fields, the process of sudden rotation of the magnetization of unfavorably oriented domains to the easy-axis direction(s) nearest to that of the applied field also becomes significant. At a given value of the magnetic field (labeled H_s), saturation is finally achieved ($M = M_s$, defined in eqn [13]), mainly by coherent rotation of the domain magnetization toward the applied field direction. For $H > H_s$, the $M(H)$ curve is flat since the applied field is already strong enough to align all the elementary dipoles in the sample along its direction.

Figure 7 “Virgin” magnetization curve of a ferromagnet. The main mechanisms by which the magnetization process advances for several applied field values are indicated.

Figure 8 Schematic view of the main mechanisms by which the magnetization process advances for several applied field values.

If the value of the applied field is now reduced to zero, it is noticed that the obtained $M(H)$ curve does not coincide with the previous one apart from a small region near H_s . In particular, the magnetization at zero applied field does not go back to zero (retentivity), and its value M_R is called remanence or remanent magnetization. In order to force the magnetization to zero, it is necessary to apply a magnetic field H_C in the opposite direction; this value is called coercivity or coercive field. (Some authors make use of a distinction between remanence/coercivity (indicating the sample behavior after it has reached saturation) and remanent

magnetization/coercive field (relative to a magnetization curve reaching an arbitrary value $M < M_S$.) Raising the reverse field strength to H_S leads to the saturation of the magnetization in the opposite direction as before. Reversing the field once again, one obtains the so-called hysteresis loop (Figure 9).

While “hard” magnetic materials (i.e., those displaying a large coercivity) are generally useful as permanent magnets or for memory-storage purposes (in order to avoid demagnetization due to stray magnetic fields), “soft” ones may be good candidates for the realization of power transformers or electromagnets. In the former case, apart from retentivity, coercivity, and Curie temperature, another figure of merit which is often used in practice is the maximum energy product $BH_{\max}$, which is the maximum value of the product $\mathbf{B} \cdot \mathbf{H}$ in the demagnetizing quadrant ($M > 0, H < 0$) of the hysteresis curve. This corresponds to the energy stored in the considered material within a magnetic circuit operating at an optimized workpoint, and should not be confused with the energy lost due to the irreversible processes during one hysteresis loop, that is,

$$\oint \mathbf{B} \cdot d\mathbf{H} \quad [31]$$

Magnetization Rotation and Anisotropy

Most of the energy loss during the hysteresis cycle occurs at low fields as a result of irreversible domain boundary motion, due to inhomogeneous microstrains (dislocations) which obstructs the rotation of the magnetic moments. On the other hand, processes involving domain rotation are governed by a competition between the anisotropy and the Zeeman energy $E_Z = -\mu_0 \mathbf{H} \cdot \mathbf{M}$. To study the role of anisotropy in determining the shape of the magnetization curve, assume that the boundary motion of domain walls can be achieved with a negligibly small magnetic field. In the case of a uniaxial sample, $M(H)$ can be found by minimizing

$$E_A + E_Z = \sum_n K_n \sin^{2n} \theta - \mu_0 \mathbf{H} \cdot \mathbf{M} \quad [32]$$

Let θ be the angle between the magnetization vector and the c -axis, which will be considered also as the EMD, for simplicity. If $\mathbf{H}$ is applied along the c -axis, both E_A and E_Z are minimized $\mathbf{M} \parallel \mathbf{H}$ and saturation is reached immediately when the external applied field is equal to the demagnetizing field. If $\mathbf{H}$ is applied perpendicularly to the easy-axis, differentiating eqn [32] and knowing that $M = M_S \sin \theta$ leads to

$$HM_S = \sum_n 2nK_n \left(\frac{M}{M_S} \right)^{2n-1} \quad [33]$$

an implicit expression for the magnetization curve. By putting $M = M_S$, one can immediately find

$$H_S = \frac{2}{M_S} \sum_n nK_n \quad [34]$$

and

$$\left. \frac{dM}{dH} \right|_{H=0} = \frac{M_S^2}{2K_1} \quad [35]$$

Similar calculations can be made for any other orientations of the field and of the EMD, leading to the remarkable result that, in principle, complete saturation cannot be achieved if $\mathbf{H}$ is not parallel to an “extremal” direction (i.e., one which minimizes or maximizes the anisotropy energy).

Figure 9 Hysteresis cycle of a ferromagnet. Remanence (M_R) and coercivity (H_C) are indicated on the graph axes.

Introduction

The quantum theory of magnetism has been developed from two opposite starting points. One is the localized-electron model, where the electrons remain on the atoms in the crystal and contribute to magnetism. The intra-atomic interaction between these electrons is so strong that the magnetic moment is determined on each individual atom by Hund's rules. The interatomic exchange interaction is, on the other hand, much smaller than the intra-atomic one, and competes with thermal disorder to determine the long-range magnetic ordering. This model is applied to insulating crystals and rare-earth metals. The other model of magnetism is based on the band structure of electrons. These electrons move around in the crystal and contribute to the electric conduction. The ferromagnetic state may be stabilized for materials with a strong exchange interaction and a high density of states at the Fermi level. This is the band model or itinerant-electron model, which is commonly applied to 3d transition metals, alloys, and compounds.

In this section, magnetic properties as well as magnetic ordering are discussed for both localized-electron and itinerant-electron models. A molecular field theory is extremely useful in describing the ground state and finite temperature properties. In this approximation, the focus is on how various magnetic properties can be explained, and then, how spin wave excitations and spin fluctuations at finite temperature can be studied. SI units are used in this article. The magnetic induction, B , is given by $\mu_0(H+M)$, where H , M , and μ_0 are the magnetic field, magnetization, and permeability in vacuum, respectively. The Bohr magneton is denoted by $\mu_B = eh/2m$ in this unit system, where e and m are the charge and mass of an electron, respectively, and where h is the Planck constant divided by 2π . To avoid confusion, μ_B is taken to be positive, so that the direction of magnetization is the same as that of the spin.

Localized-Electron Model

The concept of exchange coupling between the spins of two or more nonsinglet atoms arose with the Heitler–London theory of chemical bonding and was applied in 1928 to the theory of ferromagnetism by Heisenberg. The spin Hamiltonian is given by $\mathcal{H} = -\sum_{i \neq j} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j$, where J_{ij} is the interatomic exchange integral between the electrons on atoms at $\mathbf{R}_i$ and $\mathbf{R}_j$. $\mathbf{S}_i$ and $\mathbf{S}_j$ are spin operators on these atoms. The exchange integral J_{ij} comes from the antisymmetric nature of wave functions with respect to the spatial and spin coordinates, and is given by

$$J_{ij} = \frac{e^2}{4\pi\epsilon_0} \int \int \frac{\psi_j^*(\mathbf{r})\psi_i^*(\mathbf{r}')\psi_i(\mathbf{r})\psi_j(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'-\mathbf{R}_i+\mathbf{R}_j|} d\mathbf{r}d\mathbf{r}'$$

where $\psi_i(\mathbf{r})$ is the wave function on the atomic site $\mathbf{R}_i$. The value of J_{ij} becomes small obviously when $|\mathbf{R}_i-\mathbf{R}_j|$ is large, as $\psi_i(\mathbf{r})$ is localized on the atom at $\mathbf{R}_i$ in this model. Here, J_{ij} is assumed to take a constant value, J for the nearest neighbor atomic pair at $\mathbf{R}_i$ and $\mathbf{R}_j$, and to be zero for other pairs. In this case, the Hamiltonian is written by $\mathcal{H} = -2J\sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j$, where $\langle ij \rangle$ on the summation denotes the sum over nearest neighbor pairs at $\mathbf{R}_i$ and $\mathbf{R}_j$.

Ferromagnetism

Before the concept of quantum mechanics had been established, Weiss proposed in 1907 a very successful description of ferromagnetism by introducing a molecular field acting on atomic magnetic moments, which is assumed to be proportional to

the net magnetization. The origin of the molecular field is nowadays known to be a quantum mechanical exchange interaction. A material, which consists of the same type of atoms, is considered. When the magnetic field is applied to the z direction (quantized axis of spin), the average value (or expectation value) of the spin operator S_i has a z component $\langle S_z \rangle$ only. The magnetization is now written as $M = Ng\mu_B \langle S_z \rangle$, where N is the number of atoms in the material, $g = 2$ (g -factor for spin system), and μ_B is the Bohr magneton. The term $S_i \cdot S_j$ in the Hamiltonian is approximately written by $S_i \cdot S_j \simeq \langle S_z \rangle S_{j,z} + S_{i,z} \langle S_z \rangle - \langle S_z \rangle^2$. One gets, together with the Zeeman energy by the magnetic induction B , $\mathcal{H} \simeq -2zJ \langle S_z \rangle \sum_i S_{i,z} - g\mu_B B \sum_i S_{i,z} + NzJ \langle S_z \rangle^2 = -g\mu_B B_{\text{eff}} \sum_i S_{i,z} + NzJ \langle S_z \rangle^2$, where z is the number of the nearest neighbor atoms in the crystal. Here, J is taken to be positive as the ferromagnetic state is discussed. The effective magnetic field is given by $B_{\text{eff}} = 2zJ \langle S_z \rangle / g\mu_B + B$. The first term $2zJ \langle S_z \rangle / g\mu_B$ corresponds to the molecular field proposed by Weiss. The molecular field coefficient ω , defined by $B_{\text{eff}} = \omega M + B$, is given by $\omega = 2zJ / N(g\mu_B)^2$.

The magnetic quantum number m_S on an atom may take $S, S-1, \dots, -S$. The average value $\langle S_z \rangle$ is evaluated by the standard statistics as $\langle S_z \rangle = SB_S(g\mu_B B_{\text{eff}} / k_B T)$ at finite temperature T , where $B_S(x)$ is the Brillouin function defined by

$$B_S(x) = \frac{2S+1}{2S} \coth\left(\frac{2S+1}{2S}x\right) - \frac{1}{2S} \coth\left(\frac{x}{2S}\right)$$

where $x = g\mu_B B_{\text{eff}} / k_B T$ and k_B is the Boltzmann constant. (In the limiting case of $S = \infty$, $B_S(x)$ becomes the Langevin function, which appears when $S_{i,z}$ is treated as a classical spin vector.) The average value $\langle S_z \rangle$ is obtained as a function of T and B by solving the equation for $\langle S_z \rangle$ self-consistently, as the argument in the Brillouin function contains $\langle S_z \rangle$ itself. Figure 1 shows the calculated result of the magnetization for $S = 5/2$ as a function of T and B . T_C is the Curie temperature where $\langle S_z \rangle$ becomes zero at $B = 0$. The T -dependence of M at $B = 0$ is very weak at low T in this theory, being different from the observed results. At low T , M decreases with increasing T as $T^{3/2}$ by the thermal excitations of spin waves. This is discussed in the subsection, "Spin waves."

The susceptibility $\chi_p (= \mu_0 M / B)$ above T_C is written at high T as $\chi_p = \mu_0 C / (T - T_C)$. This is called the Curie-Weiss law. Here, T_C and C are the Curie temperature and the Curie constant respectively, given by $T_C = 2zJS(S+1)/3k_B$ and $C = N(g\mu_B)^2 S(S+1)/3k_B$. This is derived by using the approximation $B_S(x) \sim x(S+1)/3S$ at small x . At $T = T_C$, M is proportional to $B^{1/3}$. Then, the susceptibility χ_p diverges as $B^{-2/3}$ when B tends to zero. The critical index δ , defined by $M \propto B^{1/\delta}$, is 3 in the molecular field theory. However, the observed result of δ for conventional ferromagnets is ~ 4 . The molecular field theory breaks down at $T \simeq T_C$.

Antiferromagnetism

The crystal, which consists of two equivalent sublattices A and B, may have an antiferromagnetic spin structure when the exchange integral J_{AB} between the nearest neighbor spins on the different sublattices is negative. Sublattice moments are given by $M_A = Ng\mu_B \langle S_z^A \rangle / 2$ and $M_B = Ng\mu_B \langle S_z^B \rangle / 2$, where the number of atoms on each sublattice is $N/2$. Here, S_z^A and S_z^B are the z components of S on these sublattices. Magnitudes of M_A and M_B without magnetic fields are equal to M , that is, $M_A = -M_B = M$.

Effective fields acting on the A and B sublattice spins are written by $B_{\text{eff}}^A = -\omega' M_A - \omega M_B + B$ and $B_{\text{eff}}^B = -\omega M_A + \omega' M_B + B$, where ω and ω' are the molecular field coefficients of inter- and intra-sublattice moments given by $\omega = 4z_{AB}J_{AB}/N(g\mu_B)^2$ and $\omega' = 4z_{AA}J_{AA}/N(g\mu_B)^2$. Here, $J_{AA} (= J_{BB})$ is the intra-sublattice exchange integral and z_{AB} and $z_{AA} (= z_{BB})$ are the numbers of the nearest neighbor atoms on the different sublattices and on the same sublattice. By the same procedure as used in the ferromagnetic

Figure 1 Temperature and field dependences of the magnetization M for $S = 5/2$. $\tilde{M} = M / Ng\mu_B S$, $\tilde{T} = T / T_C$ and $\tilde{B} = g\mu_B B / 2zJS$.

case, the thermal averages $\langle S_z^A \rangle$ and $\langle S_z^B \rangle$ are obtained by the Brillouin function as $\langle S_z^A \rangle = SB_S(x_A)$ and $\langle S_z^B \rangle = SB_S(x_B)$, where $x_A = g\mu_B SB_{\text{eff}}^A/k_B T$ and $x_B = g\mu_B SB_{\text{eff}}^B/k_B T$. The Néel temperature T_N , where the sublattice moment at $B = 0$ vanishes, is given by $T_N = 2S(S+1)(z_{AB}|J_{AB}| + z_{AA}J_{AA})/3k_B$. Solving the simultaneous equations for M_A and M_B , the susceptibility $\chi_p(T)$ above T_N is obtained as $\chi_p(T) = \mu_0 C/(T + \Theta_p)$, where $\Theta_p = 2S(S+1)(z_{AB}|J_{AB}| - z_{AA}J_{AA})/3k_B$ and $C = N(g\mu_B)^2 S(S+1)/3k_B$. At $T = T_N$, $\chi_p(T_N)$ is given by $\chi_p(T_N) = \mu_0/\omega$. When $J_{AA} = 0$, T_N is equal to Θ_p . The observed value of T_N for conventional antiferromagnets is smaller than that of Θ_p .

Below T_N , there are two kinds of susceptibility. One is the susceptibility when the magnetic field is applied along the direction of M_A . In this case, M_A increases by $\delta M_{\parallel}/2$, and M_B shrinks by $\delta M_{\parallel}/2$. $\delta M_{\parallel}$ is obtained by solving simultaneous equations of M_A and M_B given by the Brillouin functions with B_{eff}^A and B_{eff}^B . Noting that $M_A = -M_B = M$ at $B = 0$, one gets the susceptibility $\chi_{\parallel}(T) (= \mu_0 \delta M_{\parallel}/B)$ parallel to the sublattice moment as $\chi_{\parallel}(T) = \mu_0 C / \{\Theta_p + (S+1)T/3SB'_S(x)\}$, where $x = 6MT_N/Ng\mu_B(S+1)T$ and $B'_S(x)$ is the derivative of $B_S(x)$ with respect to x . At $T = 0$, $\chi_{\parallel}(0) = 0$ as $\lim_{T \rightarrow 0} T/B'_S(x) = \infty$. At $T = T_N$, $\chi_{\parallel}(T_N) = \chi_p(T_N) = \mu_0/\omega$ as $B'_S(0) = (S+1)/3S$. The other is the susceptibility when the magnetic field is applied in the perpendicular direction to M_A and M_B . In this case, the induced moment $\delta M_{\perp}/2$ appears on each sublattice in the field direction. The susceptibility $\chi_{\perp} (= \mu_0 \delta M_{\perp}/B)$ perpendicular to the sublattice moment is obtained by the balance of effective fields shown in Figure 2. The sublattice moments rotate by an angle θ so that $\mathbf{B} - \omega(\mathbf{M}_A + \mathbf{M}_B) = 0$. One gets $\chi_{\perp} = \mu_0/\omega$, which does not depend on T and also on the value of ω' . In Figure 3, $\chi_{\parallel}(T)$ and $\chi_{\perp}(T)$ below T_N , and $\chi_p(T)$ above T_N are shown as a function of T for $S = 5/2$ and $\omega' = 0$. For polycrystalline or powder samples, the antiferromagnetic moments in domains or particles will orientate in random directions, so that $\chi(T) = \chi_{\parallel}(T)/3 + 2\chi_{\perp}(T)/3$ below T_N .

Magnetizing Process of Antiferromagnets

For the magnetizing process of antiferromagnets, magnetic anisotropy plays an important role. The magnetic moment prefers to align in a certain crystallographic direction without a magnetic field. For the sake of simplicity, consider the case of uniaxial anisotropy. Taking the easy axis of magnetization along the z -axis, the sublattice moment M_A prefers to align in the positive (negative) z direction and M_B in the negative (positive) z direction. The anisotropy energy is phenomenologically given by $E_{\text{ani}} = -(K_u/2)(\cos^2\theta_A + \cos^2\theta_B)$, where θ_A and θ_B are angles between the sublattice moments and the easy axis. The coefficient K_u is called the uniaxial anisotropy constant. The anisotropy fields, B_{ani}^A and B_{ani}^B acting on the A and B sublattice moments, are defined by $B_{\text{ani}}^A = K_u M_A^z/M^2$ and $B_{\text{ani}}^B = K_u M_B^z/M^2$.

Figure 2 Magnetic induction B of the applied field and molecular fields $-\omega M_A$ and $-\omega M_B$ on the sublattice moments M_A and M_B , respectively. $\delta M_{\perp}$ is the induced moment.

Figure 3 Parallel and perpendicular susceptibilities $\tilde{\chi}_{\parallel}(T)$ and $\tilde{\chi}_{\perp}(T)$ below T_N , and of $\tilde{\chi}_p(T)$ above T_N for $S = 5/2$ and $\omega' = 0$. $\tilde{\chi}_{\parallel}(T) = \chi_{\parallel}(T)/\chi_p(T_N)$, $\tilde{\chi}_{\perp}(T) = \chi_{\perp}(T)/\chi_p(T_N)$, $\tilde{\chi}_p(T) = \chi_p(T)/\chi_p(T_N)$, and $\tilde{T} = T/T_N$.

The induced moment $\delta M_{\perp}$ by the field applied perpendicular to the z -axis (hard axis of magnetization) is suppressed by the anisotropy field. The susceptibility $\chi_{\perp}$ is given by $\chi_{\perp} = \mu_0/(\omega + K_u/2M^2)$. This is derived in the following way. E_{ani} is rewritten as $(K_u/2)(\sin^2\theta_A + \sin^2\theta_B) - K_u$. The anisotropy field to the hard axis of magnetization is written by $-K_u\delta M_{\perp}/2M^2$ (negative field), and then one can get the above expression of $\chi_{\perp}$. On the other hand, when the magnetic field is applied along the easy axis of magnetization and when the sublattice moments align in the hard axis, the induced moment $\delta M_{\perp}$ in the field direction is enhanced by the anisotropy field. The susceptibility, in this case, is written by $\chi'_{\perp} = \mu_0/(\omega - K_u/2M^2)$.

When the magnetic field is applied along the easy axis of magnetization, the magnetic energy together with E_{ani} is approximately given by $\Delta E_{\parallel} = -\chi_{\parallel}(T)B^2/2\mu_0 - K_u$ at low fields. On the other hand, when the magnetic field is applied along the easy axis of magnetization and when the sublattice moments align in the hard axis, the magnetic energy is given by $\Delta E_{\perp} = -\chi'_{\perp}(T)B^2/2\mu_0$. At weak magnetic fields applied along the direction of the easy axis, the sublattice moments keep to align in the easy axis by the gain of the anisotropy energy. However, under strong magnetic fields they may align in the direction perpendicular to the magnetic field, as $\chi'_{\perp}$ is larger than $\chi_{\parallel}$, and then, $\Delta E_{\perp}$ becomes lower than $\Delta E_{\parallel}$. That is, a spin flipping takes place from the parallel direction to B to the perpendicular one at a certain magnetic field. The critical value B_{sf} of the spin flipping is given by the equation $\Delta E_{\parallel} = \Delta E_{\perp}$, and one obtains $B_{\text{sf}}(T) = [2\mu_0 K_u / \{\chi'_{\perp}(T) - \chi_{\parallel}(T)\}]^{1/2}$. At $T = 0$, B_{sf} is written by $B_{\text{sf}} = \{B_{\text{ani}}(2B_{\text{ex}} - B_{\text{ani}})\}^{1/2}$, where $B_{\text{ex}} = \omega M$ and $B_{\text{ani}} = K_u/M$. When $B > 2B_{\text{ex}} - B_{\text{ani}}$, the sublattice moments become parallel to each other. The critical value is denoted by $B_c (= 2B_{\text{ex}} - B_{\text{ani}})$. The spin structures are the antiferromagnetic one at $B < B_{\text{sf}}$, the canted one at $B_{\text{sf}} < B < B_c$ and the ferromagnetic one at $B > B_c$. When T increases, B_c decreases, while B_{sf} increases slightly, as shown in Figure 4.

When B_{ani} is larger than B_{ex} , the canted spin state does not appear. The magnetization curve at $T = 0$ shows a jump from the antiferromagnetic state to the ferromagnetic one at $B = B_{\text{ex}}$. This is a field-induced metamagnetic transition. However, the transition at finite T becomes gradual at B_{ex} , as shown in Figure 5. When the magnetic field is applied to the hard axis of magnetization, the induced moment $\delta M_{\perp}$ increases as $\chi_{\perp}B/\mu_0$ up to $B'_c = 2B_{\text{ex}} + B_{\text{ani}}$ and saturates to $2M$.

Spin Waves

The low-lying energy states of spin systems coupled by exchange interactions are wave-like, as originally discussed by Bloch. This is called a spin wave or a magnon. Spin waves have been studied for all types of ordered spin arrays. In this subsection, the ferromagnetic spin wave is studied.

The energy associated with nonuniform distributions of the spin direction is given by the Heisenberg exchange energy $W = -J \sum_i \sum_{\delta} \mathbf{S}_i \cdot \mathbf{S}_{i+\delta}$, where δ is the nearest neighbor vector of $\mathbf{R}_i$. Here, the $\mathbf{S}$ s are quantum mechanical spin operators. They are treated as if they were classical vectors. $\mathbf{S}_{i+\delta}$ is expanded in a Taylor series as $\mathbf{S}_i + (\delta \cdot \nabla) \mathbf{S}_i + (1/2)(\delta \cdot \nabla)^2 \mathbf{S}_i$. For lattices with inversion symmetry, the first-order term in δ is cancelled out by the summation over δ , and one gets $W = -J \sum_i |\mathbf{S}_i|^2 - (J/2) \sum_i \sum_{\delta} \mathbf{S}_i \cdot \{(\delta \cdot \nabla)^2 \mathbf{S}_i\}$. It is noted here that $\nabla^2(\mathbf{S}_i \cdot \mathbf{S}_i) = 0$, as $|\mathbf{S}_i|^2$ is a constant. Then, one can get the exchange energy for the local magnetization $\mathbf{M}(\mathbf{r}) = g\mu_B \sum_i \mathbf{S}_i \delta(\mathbf{r} - \mathbf{R}_i)$ as $E_{\text{ex}} = (1/2V)D \int |\nabla \mathbf{M}(\mathbf{r})|^2 d\mathbf{r}$, where $|\nabla \mathbf{M}(\mathbf{r})|^2 = \sum_{\alpha} \{(\partial M_{\alpha}/\partial x)^2 + (\partial M_{\alpha}/\partial y)^2 + (\partial M_{\alpha}/\partial z)^2\}$, $\alpha = x, y, z$, and V the volume of the sample. The coefficient D in E_{ex} is called the Landau-Lifshitz constant. The exchange field is defined by $\mathbf{B}_{\text{ex}}(\mathbf{r}) = \partial E_{\text{ex}}/\partial \mathbf{M}(\mathbf{r})$. Neglecting the boundary effects, one gets $\mathbf{B}_{\text{ex}}(\mathbf{r}) = D \nabla^2 \mathbf{M}(\mathbf{r})$. Then, the torque equation is given by

Figure 4 Temperature and field dependences of the induced moment M_{ind} for $S = 5/2$, $\omega' = 0$, and $2K_u/Nz_{\text{AB}}|J_{\text{AB}}|S^2 = 0.2$. $\tilde{M}_{\text{ind}} = 2M_{\text{ind}}/Ng\mu_B S$, $\tilde{T} = T/T_N$, and $\tilde{B} = g\mu_B B/2z_{\text{AB}}|J_{\text{AB}}|S$.

Figure 5 Temperature and field dependences of the induced moment M_{ind} for $S = 5/2$ and $\omega' = 0$ for the case of the strong anisotropic field ($B_{\text{ani}} > B_{\text{ex}}$). $\tilde{M}_{\text{ind}} = 2M_{\text{ind}}/Ng\mu_B S$, $\tilde{T} = T/T_N$, and $\tilde{B} = g\mu_B B/2z_{AB}|J_{AB}|S$.

$\partial \mathbf{M}(\mathbf{r}, t)/\partial t = \gamma \mathbf{D} \mathbf{M}(\mathbf{r}, t) \nabla^2 \mathbf{M}(\mathbf{r}, t)$, where γ is the gyromagnetic ratio $g\mu_B/\hbar$. One looks for travelling wave solutions of the form $M_x(\mathbf{r}, t) = \delta m_x \exp\{i(\mathbf{q} \cdot \mathbf{r} - \omega t)\}$, $M_y(\mathbf{r}, t) = \delta m_y \exp\{i(\mathbf{q} \cdot \mathbf{r} - \omega t)\}$ and $M_z \simeq M_s$. One gets $\hbar\omega_q = g\mu_B D M_s q^2$ for small q . The coefficient of q^2 is called the exchange stiffness constant, which is observed by neutron scattering and spin wave resonance measurements. A schematic representation of $\mathbf{M}(\mathbf{r}, t)$ at a fixed time t is shown in Figure 6.

The wave of local magnetization, that is, the spin wave is quantized. By the analogy with phonons, the Hamiltonian for the quantized spin wave (magnon) is written by $\mathcal{H} = \sum_q (n_q + 1/2) \hbar\omega_q$ where n_q is the occupation quantum number of magnons with the wave-number vector $\mathbf{q}$. The temperature dependence of the magnetization is given by $M(T) = M_s - 2\mu_B \sum_q \langle n_q \rangle$, where M_s is the spontaneous magnetization and the thermal average $\langle n_q \rangle$ is a Bose distribution function $\{\exp(\hbar\omega_q/k_B T) - 1\}^{-1}$. One obtains $\Delta M(T) = M_s - M(T) \propto T^{3/2}$ at low temperature where $\hbar\omega_q$ is proportional to q^2 . The theory of spin waves is also established in the itinerant-electron model of magnetism.

Itinerant-Electron Model

A quantum theory of ferromagnetism of conduction electrons in metals began with Bloch's paper in 1929. A free-electron gas with sufficiently low density was shown to be ferromagnetic. This means that the carriers of the magnetic moment in metals also participate in electric conduction. In 1933, Stoner pointed out that nonintegral values of the observed magnetic moment per atom

Figure 6 Schematic representation of the spin wave with wave-number vector $\mathbf{q}$.

in 3d transition metals is explained if 3d electrons are itinerant, having a suitable density of states (DOS) and an exchange interaction parameter. Slater discussed ferromagnetism of Ni metal, using calculated results of the electronic structure and estimating the exchange couplings between electrons from spectroscopic data.

The subsequent development of itinerant-electron magnetism has proceeded mainly along two lines. One is the study on refinements of the electronic structure. The other is the study on the interaction between electrons. For both studies, electron correlations make the problem difficult. In the former, the electron correlations are taken into account in the potential of the electrons. A local spin-density functional formalism for the band calculation is established. Ferromagnetic, antiferromagnetic, and spin-density wave states are discussed for real materials by this formalism. In the latter, the interaction between electrons is treated as a many-body problem. To discuss the electron correlations, the Hubbard Hamiltonian is often made use of.

Band Theory of Ferromagnetism

The band theory (or Stoner theory) is widely used in the study of magnetism for transition metals, alloys, and compounds. In the original paper of Stoner, the DOS of electrons is assumed to be a parabolic one with respect to the energy. However, the DOS for actual transition metals is not so simple, but has a lot of peaks, as many energy levels overlap with one another. Figure 7 denotes the calculated DOS curve for a b.c.c. Fe metal in the nonmagnetic state at the lattice constant 28.5 nm. E_F denotes the Fermi level. Electrons occupy energy levels up to E_F .

The Pauli spin susceptibility is written in terms of the DOS curve, $D(E)$, as $\chi_0(T) = 2\mu_0\mu_B^2[D_0 - (\pi^2 k_B^2 T^2/6)\{D_0''/D_0 - D_0'/D_0'\}]$ at low T , where D_0 , D_0' and D_0'' are the values of $D(E)$ at E_F and the first and second derivatives of $D(E)$ with respect to E at E_F , respectively. The T -dependence comes from the low temperature expansion of the integrals connected with the Fermi distribution function. One takes into account the exchange interaction by the molecular field approximation. The induced magnetic moment, M , by the external field is given by $M = \chi_0(T)(B+IM)/\mu_0$, where I is the molecular field coefficient. Then, the susceptibility $\chi(T) (= \mu_0 M/B)$ is obtained as $\chi(T) = \chi_0(T)/\{1 - I\chi_0(T)/\mu_0\}$. The factor $1/\{1 - I\chi_0(T)/\mu_0\}$ is the exchange-enhancement factor of the susceptibility. When the value of I is so large that the denominator in the enhancement factor becomes zero, the susceptibility $\chi(T)$ diverges. This is the magnetic instability in the paramagnetic state, which is called the Stoner condition for the appearance of ferromagnetism.

When $I\chi_0(0)/\mu_0 > 1$, the ferromagnetic state is stable at $T = 0$. In this case, the Curie temperature T_C is obtained by $I\chi_0(T_C)/\mu_0 = 1$. In the native Stoner theory, the value of I is an adjustable parameter to fit the Curie temperature. However, the value of I is nowadays obtained by the local spin-density functional formalism of the band calculation. The value of T_C estimated with the calculated value of I is much larger than the observed one, although reasonable values of the magnetic moment for 3d transition metals are obtained. This is because the effect of spin fluctuations at finite temperature is not taken into account in the theory.

Description of Ferromagnetism by the Landau Theory

By the fixed-spin-moment method developed recently, the magnetic energy $\Delta E(M)$ can be calculated numerically as a function of the magnetic moment M . The open circles in Figure 8 denote the calculated results of $\Delta E(M)$ for a b.c.c. Fe metal at the lattice constant 28.5 nm. The equilibrium state is achieved at $M \sim 2.2\mu_B$ per Fe atom, being very close to the observed one. The calculated $\Delta E(M)$ can be fitted in the form of $\Delta E(M) = (a_0/2)M^2 + (b_0/4)M^4$, as shown by the dotted curve in the figure. This is just the Landau expansion of the magnetic energy. For some materials, the calculated $\Delta E(M)$ is expanded up to much higher order terms of M .

The Landau coefficients a_0 and b_0 are also obtained by the Stoner theory. At $T = 0$ they are written by $a_0 = [1/2D_0 - I]/\mu_0\mu_B^2$ and $b_0 = [3D_0^2/D_0^2 - D_0''/D_0]/48D_0^3/\mu_0\mu_B^4$. These expressions of a_0 and b_0 are derived by a rather crude approximation of the rigid band

Figure 7 DOS curve for a b.c.c. Fe metal in the nonmagnetic state. E_F denotes the Fermi level. The value of D_0 is $2.05 \text{ eV}^{-1} \text{ atom}^{-1} \text{ spin}^{-1}$. The unit of energy 1 eV is $1.602 \times 10^{-19} \text{ J}$.

Figure 8 Magnetic energy $\Delta E(M)$ as a function of M^2 for a b.c.c. Fe metal. The unit of energy 1 eV is 1.602×10^{-19} J. The dotted curve denotes the form of $\Delta E(M) = (a_0/2)M^2 + (b_0/4)M^4$ with $a_0 = -5.5910^3 \text{ T atom } \mu_B^{-1}$ and $b_0 = 1.10 \times 10^3 \text{ T atom }^3 \mu_B^{-3}$.

model, where DOS curves in the up and down spin bands are assumed not to change their shapes from those in the paramagnetic state. Nevertheless, those expressions of a_0 and b_0 are still relevant. When E_F lies near a peak of the DOS, $D'_0 \sim 0$, and $D''_0 < 0$, the value of b_0 is positive at 0 K. On the other hand, when E_F lies near a minimum of the DOS, $D'_0 \sim 0$, and $D''_0 > 0$, b_0 is negative. Even if D_0 is so small that the Stoner condition is not satisfied, the ferromagnetic state would be stabilized when the value of b_0 is negative and large. In the case of $a_0 > 0$ and $b_0 < 0$, a magnetic field-induced metamagnetic transition from the paramagnetic state to the ferromagnetic one may take place. This is the itinerant-electron metamagnetism. Moreover, the value of I can be estimated from the calculated values of a_0 and D_0 . The evaluated value of I is 0.57 eV/atom for a b.c.c. Fe metal at the lattice constant 28.5 nm.

The magnetic equation of state is given by $B = a_0 M + b_0 M^3$, as $B = \partial \Delta E(M) / \partial M$. The spontaneous magnetic moment M_s at $B = 0$ is given by $M_s = (|a_0|/|b_0|)^{1/2}$ if $a_0 < 0$ and $b_0 > 0$. It is noted that the magnetic moment in this theory increases with increasing B even at $T = 0$. The differential susceptibility $\chi_{\text{hf}} (= \mu_0 dM/dB)$ is finite ($2\mu_0|a_0|$) at $T = 0$. This is the high-field susceptibility in the ferromagnetic state. In the localized electron model, χ_{hf} vanishes at $T = 0$. The finite value of χ_{hf} at $T = 0$ is one of the characteristics of the itinerant-electron model.

Band Theory of Antiferromagnetism

An antiferromagnetic state in the itinerant-electron model can also be described by the electronic structure. For the sake of simplicity, consider a 1D lattice, where atoms are arranged along the x direction with a lattice constant a . The wave function $\phi_k(x)$ in the nonmagnetic state is given by a Bloch function in the periodic potential by the ions. The one-electron energy $\varepsilon(k)$ is expressed with the wave number k . The wave numbers are restricted to the first Brillouin zone ($-\pi/a < k \leq \pi/a$). A schematic representation of $\varepsilon(k)$ is shown by the solid curve in Figure 9a.

When the antiferromagnetic moment is given by $M_Q(x) = M_0 \exp(iQx)$ where $Q = \pi/a$ the potential of electrons includes a term with the modulation of the wavelength $2a$. This modulated potential is treated by the perturbation theory of quantum mechanics. The wave function $\psi_k(x)$ in the antiferromagnetic state is given by a linear combination of the unperturbed wave functions $\varphi_k(x)$ and $\varphi_{k+Q}(x)$, as $\psi_k(x) = \alpha_k \varphi_k(x) + \beta_k \varphi_{k+Q}(x)$ with $|\alpha_k|^2 + |\beta_k|^2 = 1$. One gets two energy curves $E_{\pm}(k) = (1/2) [\varepsilon(k) + \varepsilon(k+Q) \pm \{(\varepsilon(k) - \varepsilon(k+Q))^2 + \Delta^2\}^{1/2}]$, where Δ is the off-diagonal matrix element of the perturbed potential. The broken curve in Figure 9a denotes $\varepsilon(k+Q)$. The two energy curves cross each other at $k = \pm Q/2$. A bandgap Δ appears at the crossing point, as shown in Figure 9b. The lower energy band $E_-(k)$ is that for electrons with up spin at the up-spin sites, or for

Figure 9 (a): One-electron energy $\varepsilon(k)$ in the nonmagnetic state, and (b): $E_{\pm}(k)$ in the antiferromagnetic state. A thin horizontal line denotes the Fermi energy.

Figure 10 Main parts of the Fermi surfaces of Cr metal. The hole surface (octahedron-like) is located around H in the Brillouin zone. The surface centered at Γ (center of the Brillouin zone) is for electrons (K Nakada, unpublished work).

electrons with down spin at the down-spin sites. The higher energy band $E_+(k)$ is that for electrons with opposite spin at the up and down spin sites. This is a simple mechanism for the appearance of the antiferromagnetic state in the band theory. It is called the split band model of antiferromagnetism.

In actual materials, the situation becomes more complicated. In Figure 10, the calculated Fermi surfaces of Cr metal in the nonmagnetic state are shown. A Fermi surface denotes the equal energy surface in the reciprocal lattice space at the Fermi level. A hole surface has the octahedron-like shape centered at the H-point in the Brillouin zone and the electron surface is centered at the Γ -point (center of the Brillouin zone). Here, H and Γ are conventional symbols labeled to the symmetry points in the Brillouin zone. When the electron surface centered at Γ is shifted toward H, some portions of the electron and hole surfaces may overlap with one another. On these overlapping surfaces, the bandgap appears and the antiferromagnetic state is stabilized. Strictly speaking, the shift of the electron surface is not exactly the same as the length between the Γ - and H-points in this case. The antiferromagnetic wave-number vector Q is slightly different from that at the H-point. Then, the spin-density wave state is stabilized in the Cr metal. This is the nesting model of the Fermi surfaces.

Spin Fluctuations

As mentioned in the section, “Band theory of ferromagnetism,” the value of T_C estimated by the calculated value of I , becomes rather higher than the observed one. This is because the excitations of the collective modes of spins are not taken into account in the

theory. The excitations of collective modes play an important role in the magnetic properties at finite temperature. In this subsection, it is studied within the phenomenological Ginzburg–Landau theory.

The magnetic free energy ΔF_m is written by $\Delta F_m = (1/V) \int d\mathbf{r} \Delta f_m(\mathbf{r})$, where the free energy density $\Delta f_m(\mathbf{r})$ is given by $\Delta f_m(\mathbf{r}) = (a_0/2)|\mathbf{m}(\mathbf{r})|^2 + (b_0/4)|\mathbf{m}(\mathbf{r})|^4 + (D/2)|\nabla \cdot \mathbf{m}(\mathbf{r})|^2$. D is the Landau–Lifshitz constant given in the section “Spin waves.” ΔF_m is rewritten by using the Fourier transformation for the i th component of the magnetization density, $m_i(\mathbf{r}) = M \delta_{i,z} + (1/V) \sum_q' m_i(\mathbf{q}) \exp(i\mathbf{q} \cdot \mathbf{r})$, where M is the bulk moment in the z direction. The prime on the summation denotes the sum over q except $q = 0$. The expression of ΔF_m contains terms up to the fourth power of $m_i(\mathbf{q})$. Among them, only the terms with even power of $m_i(\mathbf{q})$ are considered. In this case, ΔF_m is given by a functional of only M and $|m_i(\mathbf{q})|^2$.

The equation of state, defined by $B = \langle \partial \Delta F_m / \partial M \rangle$, is written as $B = a(T)M + b(T)M^3$, where $\langle \dots \rangle$ denotes a thermal average. The Landau coefficients $a(T)$ and $b(T)$ are given by $a(T) = a_0 + b_0 \{ 3 \langle (\delta m_{\parallel})^2 \rangle + 2 \langle (\delta m_{\perp})^2 \rangle \}$ and $b(T) = b_0 \cdot \langle (\delta m_{\parallel})^2 \rangle$ and $\langle (\delta m_{\perp})^2 \rangle$ are mean square amplitudes of the longitudinal and transverse magnetization densities given by $\langle (\delta m_i)^2 \rangle = (1/V) \sum_q \langle |m_i(\mathbf{q})|^2 \rangle$. The T -dependence of the Landau coefficients comes from that of the mean square amplitudes of spin fluctuations $\xi(T)^2 = \langle (\delta m_{\parallel})^2 \rangle + 2 \langle (\delta m_{\perp})^2 \rangle$. Isotropic spin fluctuations are assumed, that is, $\langle (\delta m_{\parallel})^2 \rangle = \langle (\delta m_{\perp})^2 \rangle$. In this case, the Landau coefficients are given by $a(T) = a_0 + (5/3)b_0\xi(T)^2$ and $b(T) = b_0$. The present T -dependence of the Landau coefficients is very different from that in the Stoner theory where it comes only from the Fermi distribution function. The degeneracy temperature for electrons estimated from the Fermi level is very high, and then the T -dependence in the Stoner theory is very weak in the conventional ferromagnets. Thus, the spin fluctuations are found to play a dominant role at finite T .

In the case of $a_0 < 0$ and $b_0 > 0$ the Curie temperature is given by $\xi(T_C)^2 = 3|a_0|/5b_0$ as the inverse of the susceptibility should be zero at T_C , that is, $a(T_C) = 0$. By classical thermodynamics, the mean square amplitude of thermal fluctuations is known to increase monotonically as T increases. The susceptibility (at $\xi(T)^2 = pT$) above T_C is written in the form of the Curie–Weiss law as $\chi(T) = \mu_0 C / (T - T_C)$, where $C = 3/5b_0p$, $T_C = 3|a_0|/5b_0p$, and p a positive constant. Such a Curie–Weiss law cannot be obtained in the Stoner model. By analogy with the localized-electron model, the square of the effective magnetic moment M_p^2 in the paramagnetic state, estimated from the susceptibility, is proportional to the Curie constant C . On the other hand, the square of the spontaneous magnetization is given by $M_s^2 = |a_0|/b_0$ at $T = 0$. Then, the value of $(M_p/M_s)^2$ is shown to be proportional to $|a_0|^{-1}$, and subsequently to T_C^{-1} . This type of behavior of M_p/M_s is observed for 3d transition metals, alloys, and compounds (Rhodes–Wohlfarth plot). Spin fluctuations in itinerant-electron antiferromagnets have also been studied.

Introduction

The Dirac equation for the relativistic quantum mechanical electron is most famous for having predicted the existence of antiparticles. One further important aspect of this equation is the explanation of the electron spin and the magnetic moment associated with it. When atoms are formed, the electron spins interact by means of the intra-atomic exchange interaction to produce atomic magnetic moments. The correct value of the atomic magnetic moments can be calculated empirically using Hund's rules and Pauli's principle. When atoms are brought together to form a body, the atomic wave functions change drastically: the atomic magnetic moments are, in general, reduced, but may remain finite in certain special cases such as Fe, Co, and Ni. Moreover, as soon as neighboring atoms are provided, the interatomic exchange interaction comes into play and may favor the parallel alignment of the neighboring magnetic moments. In this way, macroscopic regions of aligned magnetic moments are formed in the body, and the body is said to be in a ferromagnetic state.

This microscopic description of magnetism, based on the quantum mechanical exchange interaction, is not complete. Each individual magnetic moment can be viewed as an atomic current generating a magnetic field, which interacts with other magnetic moments and contributes another term to the total magnetic energy – the energy of the dipole–dipole interaction. This term is also called the magnetostatic energy, as it is described by the Maxwell equations of magnetostatics. In contrast to the exchange interaction, this term is purely classical. It is later shown that, depending for example on the shape and size of the body, this term perturbs the parallel alignment of the magnetic moments favored by the exchange interaction. Thus the parallel alignment does not extend over the whole body, but is restricted to elementary regions called magnetic domains. Within such domains, the magnetic moments are aligned, while the orientation of the magnetic moments changes upon moving to neighboring domains.

Another class of magnetic interactions arises because of the spin–orbit coupling also contained in the Dirac equation: magnetic anisotropies. A magnetic anisotropy energy determines one or more spatial directions along which the exchange-coupled magnetic moments within the domains prefer to be aligned, where “preferring” means that the total energy of the system is reduced when the moments point along that direction in space. Magnetic anisotropies play a crucial role in domain formation. In fact, the change of the magnetic moment direction between consecutive domains does not occur abruptly: a domain wall with finite width connects domains with different magnetic moment orientation and magnetic anisotropies stabilize this wall.

The purpose of this article is to account for the state-of-the-art knowledge on magnetic domains and the walls between them. Before going into details, it is important to estimate the energy scale of the various magnetic interactions, given by their typical strength per atom. The intra-atomic exchange interaction is of the order of eV, on a temperature scale this corresponds to 10^4 K. This energy is required to produce an excited state with no atomic magnetic moment. The interatomic exchange interaction is some 10 meV (100 K). This means that the excited state with misaligned nearest-neighbor magnetic moments is attained when the temperature exceeds some 100 K (at a temperature which is called the Curie temperature). Magnetic anisotropies range from μeV in three-dimensional solids to 0.1 meV in ultrathin films (0.01 to 1 K). The reason for this broad range is that the magnetic anisotropies are strongest when the symmetry of the system is lowered, for example, when the dimensionality is reduced. The magneto-static interaction is ~ 0.1 meV (1 K). Clearly, the interactions relevant for domain formation are much smaller than the exchange interaction. Thus, it is not immediately evident why such small energies should have an impact in determining the total energy of the system and its ground-state magnetic moment configuration. This question is also carefully investigated in the remaining sections.

The Physical Basis of Magnetic Domains

The physical basis for the explanation of magnetic domains was laid down in a paper by Landau and Lifshitz in 1935. One can consider a body in a situation where each lattice site carries a magnetic moment vector (for simplicity, a spin vector is used, noticing that, according to Dirac's theory, the two vectors are proportional to each other). One important caveat: it will turn out that the relevant length scales intervening in domain formation are large with respect to the lattice constant. On these characteristic length

scales, the number of spins is so large that one can give up the quantum description of the spin vector and consider it a classical vector. The strongest contribution to the total magnetic energy comes from the exchange interaction, which measures the energy required to turn two neighboring spins into an antiparallel configuration. If this energy is positive, the total exchange energy is minimized by a uniform spin configuration. The spin ensemble can also have a magnetic anisotropy energy contribution, which favors certain spatial directions for the spins, the so-called easy direction. In the simplest case of uniaxial anisotropy, two directions in space, say e and its negative, are energetically favored. Thus, the uniform spin configuration will be aligned either along $+e$ or along $-e$, as either of these directions minimizes the total energy arising from the exchange and the magnetic anisotropy. How stable is the resulting spin configuration with respect to rotations or spin nonuniformities? The magnetic anisotropy per spin is very small but it is not possible to rotate spins individually, as they are bound together by the exchange interaction. Thus, a rotation excitation would involve turning a macroscopically large amount of spins and this requires a large excitation energy which is not available at sufficiently low temperatures. If the body is divided into oppositely magnetized regions, it would not entail any lowering of the total energy; on the contrary, some energy must be introduced to form boundaries between oppositely magnetized regions, causing an increase of the total energy. A more complicated anisotropy term may have a larger symmetry, but in no case will the magnetic anisotropy lead to magnetic domains as there is no energy to be gained upon changing from one easy direction to another. The behavior is quite different when the dipolar interaction between the magnetic moments is considered. Each moment produces a magnetic field, which interacts with all the other magnetic moments by means of the Zeeman energy contribution. The most striking feature of this magnetostatic energy is that the magnetic fields arising from a magnetic moment are very long ranged, they decay only with the third power of the distance. This is in opposition to exchange and magnetic anisotropies, which are local. The energy due to the dipolar field is the most complicated (see Appendix A), but contains a distinct feature which makes it compete directly with the exchange interaction: one part of it favors an antiparallel alignment of the spins. Of course, the interaction is very weak, but its long-range character amplifies its role with respect to the competing exchange interaction. Thus, under certain circumstances, which Landau and Lifshitz showed to depend on the size and the geometry of the body, the dipolar interaction can provide enough energy gain to sustain a nonuniform spin configuration: magnetic domains arise.

The complexity of the dipolar field and the long-range character of the dipolar interaction makes it very difficult to find the spin configuration that minimizes the total energy. However, there are some rules of thumb that help in analyzing the physical situation. One of them is provided by eqn [3] in Appendix A. This equation has a simple meaning: the total magnetostatic energy of a body is the Coulomb energy of an effective magnetic charge distribution $\rho_M \doteq -\nabla \cdot \mathbf{M}(\mathbf{x})$, where $\mathbf{M}(\mathbf{x})$ is the magnetic moment per unit volume. Its length is determined by the total magnetic moment in a sufficiently small cell centered at $\mathbf{x}$ divided by the volume of the cell, and its direction is given by the direction of the total magnetic moments within this cell. The size of this cell has to be chosen in such a way that it is small with respect to the smallest length occurring in domain formation, that is the size of the domain wall (see next section). The effective magnetic charge is provided by the divergence of $\mathbf{M}(\mathbf{x})$, thus minimizing the magnetostatic energy means avoiding regions where $-\nabla \cdot \mathbf{M}(\mathbf{x})$ is too large. A sizeable divergence of $\mathbf{M}(\mathbf{x})$ exists, for instance, at the boundaries of a uniformly magnetized body. Such surface charges increase the energy of the uniform spin configuration above the value specified by the exchange interaction. To avoid such charges, the body can split into elementary regions of different magnetization. At the boundaries between such regions, the spin vectors make a finite angle so that the exchange energy is increased (at the walls) with respect to the uniform configuration. Despite this, Landau and Lifshitz have explicitly shown that by introducing domains, the total energy might effectively be lowered. In Appendix B, a simple case is worked out where the subtleties of such total-energy minimization calculations are shown.

At the end of this section, an example illustrating this “magnetic-charges” avoidance rule is discussed. One can compare a small ferromagnetic plaquette with square geometry and a uniform spin configuration (see Figure 1a) to an identical plaquette with a particular nonuniform spin configuration where the magnetization vector circulates along a closed path within the plaquette (Figure 1b). The spin configuration in Figure 1a contains some effective magnetic charges appearing at the boundaries perpendicular to the magnetization vector. The spin configuration in Figure 1b is a very peculiar one, the magnetization vectors between two consecutive domains are orthogonal and no divergence develops at the boundary between two consecutive domains. The spin configuration in Figure 1b is free of magnetic charges and has no magnetostatic energy. One can show that when the plaquette is sufficiently large, the gain in magnetostatic energy overcomes the cost of introducing domain walls: the configuration in Figure 1b is the ground state. Experimentally, this closed path configuration is indeed observed, see Figure 1c as an illustration. The butterfly shape of the plaquette in Figure 1c is more complicated than the square plaquette just considered. Correspondingly, the experimental domain distribution (indicated by arrows), is more complex. It is also evident from Figure 1c that similar triangular plaquettes – the wings in the figure – have a slightly different domain distribution, showing that unresolved differences play a crucial role in determining the actual domain configuration. However, one essential element dominates the central parts of both wings: the domains are arranged in such a way that the magnetization vector circulates within the plane of the plaquette, avoiding the formation of magnetic charges, in agreement with the rule of thumb.

Domain Walls

Although it is the magnetostatic energy contribution that drives the rearrangement of the spin configuration into domains, it is the magnetic anisotropy that stabilizes the walls between them and makes the whole rearrangement process possible. For the sake of simplicity, the creation of a domain wall in a one-dimensional spin chain is illustrated. One can consider a chain extending along

Figure 1 (a) and (b): Schematic domain distribution in a plaquette. In (a) the uniform magnetization produces magnetic surface charges, indicated in the figure. In (b) the magnetization vector follows a closed path, thus avoiding magnetic charges. (c) Image of the domain distribution in a plaquette with butterfly shape. The images were taken using scanning electron microscopy with polarization analysis (SEMPA). In SEMPA, a finely focused electron beam impinges onto the surface of a solid. Secondary electrons are ejected and used to map the topography of the surface while the beam is scanned across the surface. In the present case a ~ 14 nm thick Co film was deposited onto a Cu(1 0 0) surface by molecular beam epitaxy (MBE) through a mask inserted between MBE source and substrate. In this mask, a butterfly-profile was carved in by focused ion beam milling, which gives rise to the laterally patterned Co film visible in the topography image. In SEMPA, not only the secondary electron current is measured, but their spin polarization is also detected. This allows mapping the surface magnetization vector. The in-plane horizontal (M_x) and vertical (M_y) components of $\mathbf{M}$ are reproduced in (c) (the component perpendicular to the film plane vanishes). The black-white contrast is indicative of a strong magnetization in opposite directions. The Cu-substrate is nonmagnetic and appears gray. From the contrast maps of the two in-plane components, the domain distribution can be reconstructed as schematically summarized by the arrows.

the x direction with fixed-length spin vectors $S(x)$ being allowed to rotate in the y - z plane. Thus, $S = S(0, \sin\theta(x), \cos\theta(x))$, S being the (dimensionless) length of the spin vector and θ the angle between the vector S and the y direction. The variable x is allowed to assume continuous values which is equivalent to say that, if any deviation from the parallel spin alignment occurs, it occurs over spatial length scales much larger than the lattice constant a . Assuming an exchange coupling between nearest neighbors of the simple form $-J \cdot S(x) \cdot S(x+a)$ ($J > 0$ being the exchange constant), any deviation from the parallel spin alignment can be worked out to increase the exchange energy by an amount $\Delta_\Gamma = \{(\Gamma \cdot a)/2 \cdot \int dx [d\theta(x)/dx]^2\}$ with the coupling constant $\Gamma = (J/2)S^2z$ (z being the number of nearest neighbors, that is, 2 for a chain). A magnetic anisotropy term which favors the y direction for the spin is $\Delta_\lambda = (\lambda/(2a)) \int dx \sin^2\theta(x)$ with the coupling constant λ measuring the energy required to turn the spin away from the y direction. Notice that, in accordance with the above discussion, $\Gamma > \lambda$. The equilibrium $\theta(x)$ is found by setting the functional variation of $\Delta_\Gamma + \Delta_\lambda$ to zero, which produces the Euler equation of the variational problem:

$$\Gamma a \frac{d^2\theta}{dx^2} - \frac{\lambda}{a} \sin\theta \cos\theta = 0 \quad [1]$$

One can study the stability of a wall by solving this equation with the following boundary conditions: $\theta = \pi$ (0) for $x = -\infty$ ($+\infty$), and $d\theta/dx = 0$ for $x = \pm\infty$. This establishes a spin profile with domains of opposite spins on the left- and right-hand side of $x = 0$. The solution to the Euler equation with these boundary conditions exists and was found in the work of Landau and Lifshitz:

$$\cos\theta = \tanh \frac{2x}{w} \quad [2]$$

$w = 2a \cdot \sqrt{\Gamma/\lambda}$ being the width of the region near $x=0$ over which the spin rotates from one domain to the domain of opposite magnetization, that is, the domain wall width. This solution is plotted in Figure 2b as a continuous curve. The wall energy (i.e., the energy required to establish a wall) per unit wall area can be calculated analytically by inserting the solution into the total energy expression: $\sigma_w = (1/(a^{\delta-1}))\sqrt{\lambda \cdot \Gamma}$. The prefactor contains the dimensionality of the system δ . For the interaction strengths discussed in the introduction, w is expected to be of the order of some 100 lattice constants, which is a mesoscopic scale. A direct measurement of the spin profile inside the domain wall at the surface of an Fe single crystal indeed gives ≈ 200 nm. As an example, one can consider the domain image of a head-on magnetization distribution recorded in a thin epitaxial Fe film on W(1 1 0) (Figure 2a). The spatial resolution of the image is such that the continuous in-plane rotation of the magnetization

Figure 2 (a) Domain wall formation between head-on magnetized domains. The two domains, represented by different colors, are magnetized in opposite directions parallel to the horizontal axis (the [0 0 1]-direction of the cubic lattice, in this case). At the boundary between them, one recognizes that the magnetization vector rotates in the plane from one direction into the opposite one. A color code is used to represent the direction of the magnetization vector. Image size: $4.6 \times 4.6 \mu\text{m}^2$ (b) The horizontal component of the magnetization vector (divided by its value well within the domains) is plotted along an axis x , drawn perpendicular to the domain wall (full circles). At the domain boundary, the value of the component makes a transition that can be fitted by the calculated tanh - profile (continuous curve), with a characteristic wall width $w \approx 140 \text{ nm}$. To improve the statistical accuracy of the experimental profile, all experimental data points within a stripe going across the wall were averaged.

vector from one direction into the opposite direction occurring at the boundary between the two domains can be detected in detail. The rotation is illustrated with a color code explained in the caption. The experimental profile of the magnetization component that changes sign, given by the circles in Figure 2b, follows the calculated profile (continuous curve in Figure 2b), obtained by fitting the experimental data with $\tanh(2x/w)$.

An Example of Magnetic Domains: Stripes

Having established the physical basis for domain formation, the details can be worked out, which will help to achieve a deeper understanding of the energy balance which leads to domain formation. As anticipated, magnetostatic charges have to be considered, which means that the geometry and size of the body are central to the problem. For one special geometry, the appearance of domains is illustrated (for many other geometries which have been investigated so far, see the "Further reading" section). The special case of ultrathin magnetic film extending to infinity in the x_1 - x_2 plane and having a finite but small thickness d in the x_3 direction (Figure 3a) is worked out in detail. The magnetization vector is taken to be perpendicular to the film plane. The perpendicular magnetization in ultrathin films is a very special configuration, requiring a strong uniaxial magnetic anisotropy to overcome the demagnetizing effect of the dipolar interaction. This demagnetizing effect is best appreciated by comparing a uniform in-plane spin configuration with a uniform perpendicular spin configuration. The in-plane configuration has no magnetostatic energy, provided the film extends to infinity. The perpendicular configuration, on the other hand, produces opposite charges at the two boundaries of the film with vacuum. This gives rise to an electrical plane condenser geometry. Using eqn [4] in Appendix A, the magnetostatic energy (per unit area) can easily be calculated to be $2\pi M_0^2 d$ and must be overcome by a strong magnetic anisotropy favoring the perpendicular configuration in order for a perpendicular magnetization to appear.

Figure 3 (a) Schematic view of an ultrathin film (thickness d) with a stripe configuration (stripe width: L) of alternating perpendicular magnetization. The geometrical elements used in Appendix B are also indicated. (b) Room temperature SEMPA image of the stripe phase in an ultrathin ($d \approx 0.3$ nm) Fe film deposited on Cu(1 0 0) by means of MBE. The image is $92.2 \mu\text{m}$ long. The component of the magnetization vector perpendicular to the film plane is shown. The black-white contrast is indicative of oppositely magnetized stripes.

The possibility of the existence of a nonuniform perpendicular spin configuration that might lower the energy of the system with respect to the uniform configuration in the given perpendicular magnetic configuration is examined. A possible nonuniform spin configuration with perpendicular magnetization is the one consisting of stripes of opposite perpendicular magnetization running parallel to say x_2 and repeating periodically along x_1 , see Figure 3a. Such a configuration does certainly not introduce any extra magnetic anisotropy energy. Domain walls, however, are created and cause an increase of the exchange energy. The striped phase can only become energetically more favorable if the gain in magnetostatic energy is large enough to overcome the extra domain wall energy (this is shown to happen exactly in Appendix B). The stripes have an equilibrium width $L^* \propto w \cdot e^{\pi^2/2d}$. L_0 is the so-called dipolar length $L_0 \doteq \sigma_w / (2\pi M_0^2)$, and is related to the characteristic dipolar energy per atom $(2\pi M_0^2 \cdot a^3)$. Using the characteristic values as discussed in the introduction, one obtains L_0 of the order of $100a$. Thus, in the ultrathin limit $d \approx a$, the equilibrium stripe width L^* can reach astronomical values at $T = 0$: the ground state will appear to be a uniform single-domain spin configuration because the stripe width might be much larger than the size of the sample. However, when the temperature is increased, the various coupling constants renormalize and the stripe phase can penetrate the sample as its width reduces to mesoscopic lengths. This situation is indeed observed to occur in several perpendicularly magnetized ultrathin films where the stripe phase has been observed to develop. An example is given in Figure 3b for Fe films on Cu(1 0 0).

Appendix A: Magnetostatic Energy of a Localized Distribution $M(\mathbf{x})$

A useful starting point for finding the magnetostatic energy of a continuous static distribution $M(\mathbf{x})$, are the Maxwell equations of magnetostatics: $\nabla \cdot \mathbf{B} = 0$ and $\nabla \times (\mathbf{B} - 4\pi\mathbf{M}) = 0$. The magnetic field $\mathbf{H}$ defined as $\mathbf{H} \doteq \mathbf{B} - 4\pi\mathbf{M}$ can be written in terms of a magnetic potential, Φ_M : $\mathbf{H} \doteq -\nabla\Phi_M$. The first Maxwell equation now corresponds to the Poisson equation of an “effective magnetic charge” $\rho_M \doteq \nabla \cdot \mathbf{M}$: $\nabla^2\Phi_M = -4\pi\rho_M$. Thus, the magnetostatic problem has been transformed into an electrostatic problem involving charges ρ_M . Their energy amounts to (Coulomb)

$$E_M = \frac{1}{2} \int d^3x d^3y \frac{\rho_M(\mathbf{x})\rho_M(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} \quad [3]$$

This expression for E_M states that a possible way to minimize the magnetostatic energy is to avoid magnetic charges, that is to minimize the magnitude of $\rho_M \doteq \nabla \cdot \mathbf{M}$. A further useful expression for the energy involves the magnetic field $\mathbf{H}$:

$$E_M = \frac{1}{2} \int d^3x d^3y \frac{\rho_M(\mathbf{x})\rho_M(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} = \frac{1}{2} \int d^3x \rho_M(\mathbf{x})\Phi_M(\mathbf{x}) = -\frac{1}{8\pi} \int d^3x (\nabla^2\Phi_M(\mathbf{x}))\Phi_M(\mathbf{x}) = \frac{1}{8\pi} \int d^3x H^2(\mathbf{x}) \quad [4]$$

where the general solution of the Poisson equation $\Phi_M(\mathbf{x}) = \int d^3y \rho_M(\mathbf{y})/|\mathbf{x} - \mathbf{y}|$ is used. According to eqn [4], minimizing E_M means searching for a spin configuration which avoids the formation of stray fields $\mathbf{H}$.

From eqn [3], an often quoted expression for E_M can be derived. After a partial integration, the surface integral vanishes provided the magnetization distribution is localized. Using $\nabla^2 1/|\mathbf{x} - \mathbf{y}| = -4\pi\delta(\mathbf{x} - \mathbf{y})$, one obtains

$$\begin{aligned} E_M &= -\frac{1}{2} \int d^3x d^3y \mathbf{M}(\mathbf{x}) \cdot \nabla_{\mathbf{x}} \frac{\nabla_{\mathbf{y}} \cdot \mathbf{M}(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} = \frac{1}{2} \int d^3x d^3y \mathbf{M}(\mathbf{x}) \cdot \nabla_{\mathbf{x}} (\mathbf{M}(\mathbf{y}) \cdot \nabla_{\mathbf{y}} \frac{1}{|\mathbf{x} - \mathbf{y}|}) \\ &= \frac{1}{2} \int d^3x d^3y \frac{\mathbf{M}(\mathbf{x}) \cdot \mathbf{M}(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|^3} - 3 \frac{\mathbf{M}(\mathbf{x}) \cdot (\mathbf{x} - \mathbf{y}) [\mathbf{M}(\mathbf{y}) \cdot (\mathbf{x} - \mathbf{y})]}{|\mathbf{x} - \mathbf{y}|^5} + \frac{2\pi}{3} \int d^3x \mathbf{M}(\mathbf{x})^2 \end{aligned} \quad [5]$$

This equation states that the magnetic “dipole” $\mathbf{M}(\mathbf{x})$ interacts with a H field

$$\mathbf{H}(\mathbf{x}) = \int d^3y \left(-\frac{\mathbf{M}(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|^3} + 3 \frac{[\mathbf{M}(\mathbf{y}) \cdot (\mathbf{x} - \mathbf{y})](\mathbf{x} - \mathbf{y})}{|\mathbf{x} - \mathbf{y}|^5} - \frac{4\pi}{3} \mathbf{M}(\mathbf{y}) \delta(\mathbf{x} - \mathbf{y}) \right) \quad [6]$$

produced at $\mathbf{x}$ by all other dipoles at $\mathbf{y}$ (the last term is the own field of the dipole at $\mathbf{x}$). This expression for E_M is often called the dipolar energy due to the dipole–dipole interaction.

A third useful equation can be derived from eqn [4] $\int d^3x \mathbf{H} \cdot \mathbf{B} = 0$, holding for a localized distribution $\mathbf{M}(\mathbf{x})$:

$$E_M = 2\pi \int d^3x \mathbf{M}^2 \mathbf{x} - \frac{1}{8\pi} \int d^3x \mathbf{B}^2 \mathbf{x} \quad [7]$$

Accordingly, if the length of the magnetization vector is a constant, a spin configuration with a low magnetostatic energy requires maximizing the magnetic field $\mathbf{B}$.

Using the same identity, one can immediately derive

$$E_M = -\frac{1}{2} \int d^3x \mathbf{H} \cdot \mathbf{M} \quad [8]$$

Finally, one can transform eqn [7] into the interaction energy of a system of effective currents $\mathbf{J}_M \doteq c \nabla \times \mathbf{M}$. With $\mathbf{B} = \nabla \times \mathbf{A}$ and $\nabla \times (\nabla \times \mathbf{A}) = -\nabla^2 \mathbf{A}$ (in the Coulomb gauge), one obtains $\nabla^2 \mathbf{A} = -4\pi/c \mathbf{J}_M$. Finally, from this Poisson equation for $\mathbf{A}$, one can obtain

$$E_M = 2\pi \int d^3x \mathbf{M}^2 \mathbf{x} - \frac{1}{2c^2} \int d^3x d^3y \frac{\mathbf{J}_M(\mathbf{x}) \mathbf{J}_M(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} \quad [9]$$

Thus, minimizing the magnetostatic energy means searching for a spin configuration that maximizes the curl of $\mathbf{M}$.

Appendix B: The Equilibrium Stripe Width

It is very instructive for the reader to follow in detail the appearance of domains for a very specific case. One can consider perpendicularly magnetized ultrathin films of thickness d extending over a large area $\Lambda_1 \times \Lambda_2$ in the $x_1 - x_2$ plane, see Figure 3a. The magnetization within each stripe points along $\pm x_3$. The stripes of width L are taken to be parallel to x_2 . They are joined by walls with a finite width ω with $d < \omega < L$. Consecutive stripes have opposite perpendicular magnetizations. The total wall energy E_w amounts to $\sigma_w (\Lambda_1/L) \Lambda_2 \cdot d$. This is just the energy per unit wall area multiplied by the length of the wall Λ_2 , the film thickness d , and the number of walls within the length Λ_1 . Here, the wall energy per unit film area $\sigma_w d/L$ is the main interest.

The lowering of the magnetostatic energy upon introducing stripes can immediately be seen when one considers eqn [9]. A uniform perpendicular spin configuration is curl free, so that there is no effective current $\mathbf{J}_M$ anywhere in space and the total energy per unit area is simply $(2\pi M_0^2 d)$. The stripe configuration, instead, develops some curl (and correspondingly some magnetic field $\mathbf{B}$), thus necessarily lowering the magnetostatic energy.

The following calculation shows explicitly that the energy gain is enough to overcome the wall energy introduced by the stripes. First, the effective currents are found. The stripe magnetization distribution develops a curl at the boundaries (labeled with the index n) between consecutive stripes. Along these boundaries, effective current densities $\mathbf{J}_n = c j_n \mathbf{e}$ occur where $j_n = (-1)^n 2M_0/\omega$ ($n = 0, 1, \dots, (N-1)$) and $j_N = (-1)^N M_0/\omega$. One contribution to the Coulomb energy, eqn [9] arises from the interaction of each current with the remaining currents. There are Λ_1/L of such interaction terms and the calculation of this part of the interaction energy reduces to the computation of the sum of elementary integrals of the type

$$\int_{-\Lambda_2/2}^{\Lambda_2/2} \int_{-\Lambda_2/2}^{\Lambda_2/2} dx_2 dy_2 \frac{1}{\sqrt{(x_2 - y_2)^2 + L_n^2}} \quad [10]$$

($L_n = \pm nL$ and $n \neq 0$). Notice that the integration along (x_3, y_3) can be approximated by multiplying the remaining two-dimensional integrals with d^2 . This is possible because d is considered small with respect to L , so that one can set $x_3 = y_3 = 0$ in the integrand. The integration over (x_1, y_1) can be approximated by a factor w^2 , because w is considered to be much smaller than L , allowing one to set $(x_1 - y_1)^2 = L_n^2$ in the integrand. Thus, eqn [9] reduces to the elementary integral of eqn [10]. After computing these integrals, one is left with a sum that can be solved exactly because it contains in the limit $N \rightarrow \infty$ the product of Wallis. The other contribution arises

from the self energy of each current. Under the integral of the self energy, $(x_1 - y_1)$ may be smaller than $|x_2 - y_2|$. Thus, the integrations over x_1, y_1 must be performed explicitly. There are again Λ_1/L such terms and their self energy per unit area contains the integral

$$\int_0^w \int_0^w dx_1 dy_1 \int_{-\Lambda_2/2}^{\Lambda_2/2} \int_{-\Lambda_2/2}^{\Lambda_2/2} dx_2 \times dy_2 \frac{1}{\sqrt{(x_2 - y_2)^2 + (x_1 - y_1)^2}} \quad [11]$$

Summarizing all contributions, the total energy per unit film area is

$$2\pi M_0^2 d \cdot \left\{ 1 - \left[\left(\frac{3}{\pi} + \frac{2}{\pi} \ln \frac{2}{\pi} \right) \frac{2}{\pi} \ln \frac{w}{d} \right] \frac{d}{L} + \frac{2}{\pi} \frac{d}{L} \ln \frac{d}{L} \right\} + \sigma_w \frac{d}{L} \quad [12]$$

The equilibrium stripe width L^* is found by minimizing the total energy per unit area with respect to the variable $x \doteq d/L$.

$$L^* = w \cdot e^{\pi(b+1)/2} \cdot e^{\pi L_0/2d} \quad [13]$$

where the numerical factor $b = -(3/\pi + 2/\pi \ln 2/\pi)$. Notice that the equilibrium stripe width is a nonanalytic function of d for small d . It can be readily verified that the total energy of the striped phase at the equilibrium stripe width is indeed lower than the total energy of the uniform perpendicular state, by an amount $-(2/\pi)(2\pi M_0^2 d/L^*)$.

Introduction

Magnetism in matter is a purely quantum mechanical phenomenon according to the Bohr–van Leeuwens theorem: van Leeuwen demonstrated in 1918 that classical Boltzmann statistics applied rigorously to any dynamical system leads neither to a susceptibility nor to a magnetic moment, which means that classical mechanics cannot account for diamagnetism, and paramagnetism or any type of collective magnetic order. However, under the assumption that a molecule or atom has a finite magnetic moment μ , the diamagnetic and paramagnetic susceptibility was derived already in 1905 by Langevin using classical statistical thermodynamics and treating these moments without interactions. The assumption of a finite magnetic moment, however, requires quantized values for the spin S and angular momentum L that is a result of quantum mechanics. The coupling of spin and angular momentum to the total angular momentum J is a relativistic interaction, which can be treated as a perturbation for not too heavy elements (Russell Sounders or L – S coupling) and the ground state is described by Hund's rules. Accordingly, magnetism arises from quantized motions of electrons giving rise to the fundamental unit of the magnetic moment, the Bohr magneton, defined by $\mu_B = e\hbar/2m_e$ that takes the value $9.27410^{-24} \text{Am}^2 \text{or} \text{JT}^{-1}$. Thus, the magnetic moment of an atom or a molecule is given in units of μ_B (e.g., the magnetic moment of pure Fe in the metallic state is $2.2\mu_B$ per atom).

The magnetic properties of a system of electrons and nuclei are determined by the interactions of these particles with electromagnetic fields. These fields arise from two types of sources: first, there are fields due to sources external to the system such as applied electric and magnetic fields. Second, there are internal sources, which come from the charges and currents due to the particles of which the system is composed. Interactions with and between nuclear moments μ_N are not discussed here since μ_N is by a factor of ~ 1800 smaller than μ_B .

A first step is to consider the magnetic moments associated with itinerant and/or localized electrons on the respective ions of a crystal to behave completely free without interacting with each other or with their surrounding. This leads to diamagnetism and paramagnetism.

In a free atom the quantum number J , the total angular momentum, is a good quantum number, which reflects the fact that a free atom has a complete rotational symmetry in the absence of external fields and its ground state is $2J + 1$ fold degenerate. In a crystal, however, the surrounding ions produce an electric field to which the charge of the central atom adjusts and the $2J + 1$ degeneracy is removed giving rise to a splitting of the ground multiplet. The object of the crystalline electric field (CEF) theory is to describe how the moments are affected by their local environment in a crystal. Finally, one has to consider the various interactions of magnetic moments with each other leading eventually to a long-range magnetic order.

Crystalline Electric Field Interactions

The charge distribution around a central ion produces an electric field with the local symmetry of the environment. This crystal field makes a contribution to the potential energy

$$V_C(r) = \int \frac{e\rho(\mathbf{R})}{|\mathbf{r}-\mathbf{R}|} d\mathbf{R} \approx e \sum_i \frac{q_i}{|\mathbf{r}-\mathbf{R}_i|}$$

where the charge distribution $\rho(\mathbf{R})$ in the point charge model is approximated by point charges q_i at the position $\mathbf{R}_i$. The denominator may be expanded in spherical harmonics. If V_C is small compared to the spin–orbit coupling (as in the rare-earth elements where the incomplete $4f$ shell is responsible for the magnetic moment), the eigenstates are adequately accounted for by the first-order perturbation theory. Provided that the ground state and the next excited states do not mix, the matrix elements of $V_C(\mathbf{r})$

are proportional to those obtained with operator equivalents written in terms of J , which are called the Stevens operator equivalents $O_l^m(J_i)$ and the CEF Hamiltonian reads

$$\hat{H}_{\text{CF}} = \sum_i \sum_{lm} B_l^m O_l^m(J_i)$$

The CEF parameters B_l^m can, in principle, be calculated from the charge distribution of the environment, which yields reasonable results for insulators but is of limited success for metals.

The electrostatic interactions destroy the rotational symmetry of the ion and the electronic orbitals are linked to the symmetry of the lattice removing the $2J + 1$ degeneracy of the ground multiplet of the free ion. Schematically illustrated in Figure 1 is the CEF splitting (e.g., Mn in the perovskite LaMnO_3) resulting from the interaction between the nonspherical d -orbitals and the electrostatic field of the environment, which is also nonspherical. As an example, the d_{xy} -orbital in an octahedral surrounding (a) is energetically favored in comparison to the $d_{x^2-y^2}$ orbital (b) in the same environment. Those lobes, which point to neighboring charges, have higher overlap and correspond to higher electrostatic energy than those that point between. This gives rise to the CEF splitting displayed in Figure 1c.

An improvement on the point charge approximation for d -transition metal ions is the ligand field theory which is an extension of the molecular orbital theory that focuses on the role of the d -orbitals of the central ion and their overlap with orbitals on surrounding ions (ligands). Also for rare-earth compounds, CEF parameters can be calculated from first principles using the density-functional theory which, however, should be checked experimentally as, for example, by inelastic neutron scattering.

It is instructive to consider two rather different cases, namely the $3d$ -transition metal series (Fe group) and the $4f$ series (rare earth), where the relative importance of the spin-orbit coupling and CEF splitting of the ground multiplet is inverted. The spin-orbit coupling which is proportional to Z^2 (atomic number) is much larger in the $4f$ series than in the $3d$ -transition metals since rare-earth elements are significantly heavier. Furthermore, the spatial extension of the $3d$ wave functions is much more delocalized than the $4f$ wave functions that are additionally screened from CEF by the outer $6s$ - and $5d$ -shells. Thus, in rare-earth compounds CEF splitting is $\sim 10^2$ K and spin-orbit coupling of 10^4 K, which means that the Hunds rule ground state is usually observed both in metals and insulators and the effect of CEF interaction can be treated in terms of Stevens operators. In $3d$ -compounds, V_C is typically of the order of 10^4 K which is larger than the spin-orbit coupling (10^2 K) and V_C couples mainly to the orbital part of the wave function which lifts the orbital degeneracy of the $3d$ -states and Hunds rule ground state is usually not obeyed. If the CEF perturbation is strong enough and the symmetry low enough, the orbital degeneracy is completely removed. Thus, the orbital ground state is a singlet which is called the quenching of the orbital momentum (L is not anymore a good quantum number and virtually reduced to $L = 0$) and "spin-only" magnetic properties are observed. In $4d$ - and $5d$ -series (Pd and Pt groups),

Figure 1 (a) The d_{xy} -orbital is lowered in energy with respect to the $d_{x^2-y^2}$ -orbital in an octahedral environment. (b) Schematic crystal field splitting in an octahedral environment. (c) The d_{z^2} - and $d_{x^2-y^2}$ -orbitals are grouped together and called e_g levels (twofold degenerate). The d_{xy} , d_{xz} and d_{yz} are grouped together and called the t_{2g} levels (threefold degenerate).

the situation is less clear-cut because the heavier ions have a larger spin-orbit splitting, and the CEF and spin-orbit interaction can be of comparable magnitude.

The impact of CEF interaction on the magnetic properties is important and in combination with spin-orbit interaction it is the principal source of magnetic anisotropy, which is the dependence of magnetic properties on the direction in the compound. Further, properties influenced by CEF are magnetoelastic phenomena and transport phenomena as well as thermodynamic properties as the specific heat.

Origin of Long-Range Magnetic Order – Exchange Interactions

In the previous section, magnetic ions embedded in the CEF environment of the crystal were considered but the interaction between the magnetic moments was neglected. The classical interaction between two magnetic dipoles $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ at a distance r between each other is known as the dipole-dipole interaction. As the magnetic energy is $E_M = -\boldsymbol{\mu} \cdot \mathbf{H}$, the dipolar energy reads

$$E_D = \frac{\mu_0}{4\pi r^3} [\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2 - \frac{3}{r^2} (\boldsymbol{\mu}_1 \cdot \mathbf{r})(\boldsymbol{\mu}_2 \cdot \mathbf{r})]$$

Thus E_D/k_B is of the order of 1 K, if one considers two moments of $1 \mu_B$ which are separated by $1 \text{ \AA}$. Accordingly, this interaction cannot account for Curie temperatures of 1000 K, but nevertheless can become of relevance at low and ultra-low temperatures.

Dirac and Heisenberg discovered independently that electrons are coupled by exchange interactions among which direct, indirect, itinerant exchange, and superexchange can be distinguished. Direct, indirect, and itinerant exchange occurs in metallic systems. Direct and superexchange is important in nonmetallic systems.

Origin of Exchange

In order to show how the Pauli exclusion principle together with electrostatic interactions leads to magnetic effects, consider the simplest possible case – a two-electron system – where the Hamiltonian

$$\hat{H} \sum_{i=1}^2 \frac{p_i^2}{2m} + V(r_1, r_2)$$

does not depend on the spin. In quantum mechanics one cannot distinguish between identical particles, which means that the particle coordinates q_1 and q_2 can be permuted (exchanged) in the wave function and the system remains the same physically; the new wave function differs from the original one by a phase factor: $\psi(q_1, q_2) = e^{i\phi} \psi(q_2, q_1)$. Permuting once more gives the original wave function. Thus $e^{2i\phi} = 1$ and $\psi(q_1, q_2) = \pm \psi(q_2, q_1)$, which means the wave function must be either totally symmetric or antisymmetric under permutation. Electrons (Fermions) have totally antisymmetric wave functions; so the spin part must either be an antisymmetric singlet state $\chi_S (S=0)$ in the case of a symmetric spatial wave function or a symmetric spin triplet state $\chi_T (S=1)$ in the case of an antisymmetric spatial state. The overall wave function for the singlet ψ_S and the triplet state ψ_T for two electrons where both the orbital and spin part is included reads:

$$\begin{aligned} \psi_S &= \frac{1}{\sqrt{2}} \chi_S [\psi_1(r_1)\psi_2(r_2) + \psi_1(r_2)\psi_2(r_1)], \text{ with } \chi_S = \frac{1}{\sqrt{2}} (|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle) \\ \psi_T &= \frac{1}{\sqrt{2}} \chi_T [\psi_1(r_1)\psi_2(r_2) - \psi_1(r_2)\psi_2(r_1)], \text{ with } \chi_T : |\uparrow\uparrow\rangle; \frac{1}{\sqrt{2}} (|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle); |\downarrow\downarrow\rangle \end{aligned}$$

If the interaction $V = e^2/r_{12}$ is absent, then these two states would have the same energy. For $V \neq 0$, the energies of the triplet and the singlet state are different

$$\begin{aligned} E_S &= \int \Psi_S^* \hat{H} \Psi_S = U + J \\ E_T &= \int \Psi_T^* \hat{H} \Psi_T = U - J \end{aligned}$$

with

$$U = \int \int |\psi_1(r_1)|^2 V(r_1, r_2) |\psi_1(r_2)|^2 dr_1 dr_2$$

and $\delta E = E_S - E_T = 2J$

$$J = \int \int \psi_1(r_1) \psi_1^*(r_2) V(r_1, r_2) \psi_2(r_2) \psi_2^*(r_1) dr_1 dr_2$$

where J is the exchange interaction or exchange integral, and U the Coulomb integral. The original Hamiltonian does not depend on the spin but produces an energetically favorable spin configuration for parallel spins. Thus $\hat{H}$ may now be replaced by an effective one $\hat{H}^{\text{spin}}$ acting upon the spin components only with the requirement that it should produce the same $\delta E = E_S - E_T$. What will be the form of $\hat{H}^{\text{spin}}$?

For the two-electron system, the spin operators yield the following eigenvalues:

$$\hat{S}_i^2 = \hbar^2 S_i(S_i + 1) = \hbar^2 \frac{3}{4} \text{ and}$$

$$\hat{S}^2 = \hbar^2 S(S + 1) = \hat{S}_1^2 + \hat{S}_2^2 + 2\hat{S}_1 \cdot \hat{S}_2 = \hbar^2 \frac{3}{2} + 2\hat{S}_1 \cdot \hat{S}_2$$

Accordingly, the product $\hat{S}_1 \cdot \hat{S}_2 / \hbar^2 = S(S + 1)/2 - 3/4$ of both operators gives $-3/4$ for the singlet $S = 0$ and $1/4$ for triplet state $S = 1$. Hence the original spin-independent Hamiltonian can be written in the form of an effective spin Hamiltonian yielding the same eigenvalues E_S and E_T :

$$\hat{H}^{\text{spin}} = \frac{1}{4}(E_S + 3E_T) - \frac{(E_S - E_T)\hat{S}_1 \cdot \hat{S}_2}{\hbar^2}$$

$$\hat{H}^{\text{spin}} = U - J\hat{S}_1 \cdot \hat{S}_2$$

with $U = 1/4(E_S + 3E_T)$ and $J = (E_S - E_T)/\hbar^2$. If $J > 0$, $E_S - E_T > 0$ and the "parallel" coupling of the spins in the triplet state with $S=1$ is favored, while for $J < 0$ the "antiparallel" coupling in the singlet state is favored.

The generalization of this simple relation for the two-electron system to a many-body system is far from trivial. The result is the Heisenberg Hamiltonian

$$\hat{H}_{\text{Heisenberg}} = -\sum_{i>j} J_{ij} \hat{S}_i \cdot \hat{S}_j$$

where J_{ij} is the exchange interaction between the i th and j th spins. Frequently, J_{ij} is taken as a constant for the nearest neighbors (and next nearest neighbors) and zero otherwise. J_{ij} is of the order of 10^2 – 10^3 K for direct exchange in 3d-compounds, 10 – 10^2 K for indirect exchange and superexchange. A reliable calculation of J_{ij} is a rather complex task in general.

A simple but straightforward approach to obtain a convenient expression for the exchange interaction is the mean field approximation where the exchange interaction between the i th spin and its neighbors $\sum_j J_{ij} \hat{S}_j$ is approximated by a phenomenological molecular field H_m acting upon S_i . In the Weiss molecular field model, the molecular field is set proportional to the magnetization $H_m = \lambda M$, where the molecular field constant λ is determined by the exchange interaction yielding fields $\mu_0 H_m$ of the order of 1000 T for 3d-intermetallics such as Fe-Co alloys to account for their Curie temperatures of ~ 1000 K ($\mu H = k_B T_c$). Nevertheless, this phenomenological molecular field is a convenient fiction but not experienced by the electrons since exchange origins from Coulomb interaction.

Some general features of exchange interactions are noteworthy. If two electrons on an isolated atom are considered, J is usually positive and favors the parallel spin configuration (triplet state) associated with an antisymmetric orbital state which reduces the Coulomb repulsion by keeping them apart. This is consistent with Hund's first rule yielding maximum total spin under the constraint of the Pauli principle.

The situation is different for electrons on neighboring ions in molecules or in a solid. In contrast to the free electron description for a simple metal, the model of tightly bound electrons is used as an approximation not only for ionic solids but also for transition metal compounds. The total wave function is a linear combination of atomic orbitals (LCAO) centered on the respective ions (which has to be in overall antisymmetric realized by a Slater determinant.) The electrons can save kinetic energy by forming bonds because their common wave function is more extended than the original atomic orbital and comprises both ions. These molecular

Figure 2 Schematic energy splitting of bonding (spatially symmetric) and antibonding (spatially antisymmetric) molecular orbitals in a molecule (a) yielding a singlet ground state as, e.g., in H_2 molecule. (b) Schematic formation of the bandwidth W in a solid by the quasicontinuous distribution of the $10N$ d -states between the lower and upper bonding states of the originally discrete and degenerated $5d$ -atomic states for up and down spin of N transition metal atoms condensed to a crystal; E_b is the energy of the bonding state and E_{ab} of the antibonding state.

orbitals can be bonding (spatially symmetric) or antibonding (spatially antisymmetric) as shown schematically in Figure 2a for the hydrogen molecule. The latter are more localized associated with higher kinetic energy. This favors the “antiparallel” singlet state as observed in H_2 .

In a d -transition metal, the atomic $5N$ d -states for spin up and down give rise to a band of $10N$ levels distributed quascontinuously between the lower bonding and the upper antibonding levels yielding together with transfer integrals and hopping integrals, the bandwidth W (Figure 2b). One has to distinguish between interatomic terms of the exchange and Coulomb integrals (J_{ij} and U_{ij} , $i \neq j$) and intra-atomic terms J_{ii} and U_{ii} . According to the more or less localized character of the wave function, the interatomic terms are much weaker than the intra-atomic terms. The U terms tend to avoid two electrons with antiparallel spins in the same orbital and the exchange terms J favor electrons in different orbitals with parallel spins. The latter are about one order of magnitude smaller. Thus, one may define an average exchange energy $\bar{I}$ per pair of electrons per atom, which represents the interaction favoring “ferromagnetic” alignment. On the other hand, the transfer integrals associated with the bandwidth work in the opposite direction, since the creation of parallel spins implies the occupation of higher energies in the band (i.e., with higher kinetic energy). Following this very simplified approach, the balance between kinetic and exchange energy favors the appearance of a spontaneous magnetic order for the end of the $3d$ -elements (Cr, Mn, Fe, Co, and Ni).

A proper description is performed in terms of the density-functional theory where the exchange correlation potential is added to the Coulomb correlation, which allows a straightforward determination of the exchange correlation. This treatment is called the local spin density approximation (LSDA).

To summarize, exchange can be explained in the following way: the Pauli exclusion principle keeps the electrons with parallel spins apart and so reduces their Coulomb repulsion. The difference in energy between parallel and antiparallel spin configuration is the exchange energy. This, however, is favorable for ferromagnetism if the increase in kinetic energy associated with parallel spins does not outweigh the gain in potential energy, as in the familiar examples of the H_2 molecule or the He atom. In metallic Fe, Co, and Ni, the number of parallel spins produces ferromagnetism because the cost in kinetic energy is not as great as in some other metals, where the gain in potential energy is significant yielding a paramagnetic ground state.

Direct Exchange

If there is sufficient overlap of the relevant wave functions (e.g., $3d$ -orbitals) between neighboring atoms in the lattice, the exchange interaction is called direct exchange. Although Fe, Co, and Ni are frequently referred to as typical examples for direct exchange, the situation is not that simple because of the metallic state where magnetism of itinerant electrons plays an important role. Accordingly, both the localized and band character of the electrons involved in transition metals and their intermetallics have to be taken into account as is seen in the model of covalent magnetism for transition metal intermetallics.

Indirect Exchange in Insulators – Superexchange

Superexchange is typical for insulators or materials on the border of a metal insulator transition where the ions with a magnetic moment are surrounded by ions which do not carry a moment but mediate the exchange. This type of exchange is observed in transition metal oxides. An archetypical example is MnO where two cations (Mn_{2+} in the $3d^5$ state with $S = 5/2$) are coupled via an anion (O_{2-} in the $2p^6$ state with $S = 0$); the ground state is shown schematically in Figure 3a. Because of the overlap of the wave functions, one of the p -electrons of the anion (O_{2-}) hops over to one of the cations Mn_{2+} . The remaining unpaired p -electron on the anion enters into a direct exchange with the other cation. In principle, this exchange may be ferromagnetic or antiferromagnetic. The excited state shown in Figure 3b for an antiferromagnetic coupling is in most cases energetically in favor due to the interplay of two effects: the hopping of electrons between ligands, characterized by a hopping matrix element t being proportional to the bandwidth, and an average Coulomb interaction U between electrons on the same orbital. Superexchange involves oxygen p -orbitals and transition metal d -orbitals and is therefore a second-order process. In second-order perturbation theory, the exchange interaction is given by $J \propto -t^2/U$, and normally yields antiferromagnetic coupling.

Double Exchange

Double exchange is essentially a ferromagnetic type of superexchange in mixed-valent systems. Mixed-valency means that the transition metal ion on crystallographically equivalent lattice sites exhibits different ionic states, for instance, trivalent and tetravalent Mn in perovskites $(La,Sr)MnO_3$ or Fe^{2+} and Fe^{3+} in magnetite (Fe_2O_3). Due to the mixed valency, holes (i.e., unoccupied states) exist in the e_g states of the transition metal ion with a higher valency with respect to a cation of the same species with a lower valency. The simultaneous hopping of an electron from $Mn^{3+} \rightarrow O^{2-}$ and concomitantly from $O^{2-} \rightarrow Mn^{4+}$ is known as double or Zehner exchange. Hopping is favored if the neighboring ion is ferromagnetically aligned since kinetic energy is saved by delocalization, while it is hindered by antiferromagnetic alignment as shown schematically in Figure 4.

Indirect Exchange in Metals – RKKY Interaction

In transition metal alloys, intermetallic compounds, and diluted magnetic alloys where magnetic ions are dissolved in a weak paramagnetic or diamagnetic host (e.g., Fe–Au or Fe–Cu alloys), the magnetic moment carrying ions are separated by other ions and a direct overlap of wave functions responsible for the magnetic moment is hardly possible. Thus, the various types of indirect

Figure 3 (a) Superexchange of a transition metal oxide as, e.g., MnO in the ground state, (b) hopping of electrons in the excited state favors antiferromagnetic coupling.

Figure 4 (a) Double exchange interaction favors hopping via an anion (O²⁻) for ferromagnetic alignment of the transition metal ions by reducing kinetic energy, (b) while hopping is hindered by antiferromagnetic alignment.

exchange interactions between magnetic moments are mediated by conduction electrons polarized by the local moment, which is known as RKKY interaction according to Ruderman, Kittel, Kasuya, and Yoshida. Under the assumption of a spherical Fermi surface with radius k_F , the interaction is given by

$$J_{\text{RKKY}} \propto \frac{\cos(2k_F r)}{r^3}$$

The RKKY interaction is long ranged and oscillates as a function of the distance r from the polarizing local moment. Hence depending on the distance, the conduction electron polarization is positive or negative, yielding ferromagnetic or antiferromagnetic

Figure 5 (a) Density of states of the free electron gas in the paramagnetic state, (b) splitting of the spin up and down bands by either an external field H_0 or by an effective exchange field H_{eff} .

coupling with the next local moment at the position r , and is an important mechanism to describe complex magnetic structures. Archetypical examples are rare earths (R) and their intermetallics, where the localized $4f$ -electrons are responsible for magnetism without any overlap with their nearest-neighbor $4f$ wave functions. The $4f$ -moments in these R-intermetallics compare well with those of their free ion value of R_{3+} ions according to the Hund's rules and their Curie temperature are of the order of 10 to 10^2 K. In particular for systems containing f -electrons, the isotropic exchange interaction has to be extended by anisotropic terms. The anisotropy of the coupling is associated with the orbital moments of the electrons involved and the general exchange operator contains, besides the bilinear term $\hat{S}_i \cdot \hat{S}_j$, higher order isotropic interactions and all types of anisotropic exchange as, for example, Dzialoshinsky–Moriya exchange $\hat{S}_i \times \hat{S}_j$, which produces magnetic components perpendicular to the principal spin axis of the ferromagnetic or antiferromagnetic alignment. The $3d$ – $4f$ exchange interactions, together with CEF effects, are the origin of the large magnetic anisotropy in R- $3d$ -intermetallics needed for the high coercitivity of permanent magnets such as $\text{Nd}_2\text{Fe}_{14}\text{B}$ or SmCo_5 and $\text{Sm}_2\text{Co}_{17}$.

Exchange Interactions in Free Electron Systems – Itinerant Exchange

Paramagnetism of the free noninteracting electron gas is described by the Pauli susceptibility $\chi_p = 2\mu_B^2 N(E_F)$, which relates the paramagnetic response of the system to an external field with the density of states $N(E)$ at the Fermi energy E_F . In the paramagnetic state, the number of up and down spins is equal ($n \uparrow = n \downarrow = n/2$); thus, the magnetic moment $m = \mu_B(n \uparrow - n \downarrow)$ given by the number of unpaired spins is zero; here, it is assumed that each electron carries a magnetic moment of $1 \mu_B$, since $S = \pm 1/2$ and gyromagnetic ratio $g = 2$ which is a good approximation for conduction electrons. If an external field H_0 is applied, the energy of an electron with spin up or down is $\pm \mu_B \mu_0 H$ depending upon the orientation of the spin with respect to the field. Thus, the external field splits the up and down spin bands with respect to each other by the energy $2\mu_B \mu_0 H$ (see Figure 5) yielding a small but finite magnetic moment $m = \mu_B(n \uparrow - n \downarrow)$ and a Pauli susceptibility $\chi_p = m/\mu_0 H_0$.

In the Stoner Wohlfahrth model, the susceptibility of the interacting electron gas, χ_s , is enhanced due to exchange interactions by a factor $S = (1 - IN(E_F))^{-1}$, known as the Stoner enhancement yielding,

$$\chi_s = \frac{2\mu_B^2 N(E_F)}{1 - IN(E_F)} = \chi_p S$$

The quantity I is the Stoner exchange factor describing phenomenologically, the exchange interactions of the interacting electron gas that can be interpreted as the above mentioned average exchange per pair of electrons $\bar{I}$ favoring their ferromagnetic alignment, that is, to increase $n \uparrow$ with respect to $n \downarrow$. In a more advanced treating, $\bar{I}$ corresponds to the Hubbard U which models the Coulomb interaction in the Hubbard Hamiltonian in combination with the hopping integrals t . If $IN(E_F)$ approaches 1, χ_s diverges and a second-order phase transition into a magnetically ordered state takes place. Thus $IN(E_F) \geq 1$ is the Stoner criterion for the onset of magnetism. That means for transition metals: a reasonably high density of states at E_F due to narrow enough d -bands together with exchange is needed for magnetic order. By analogy to the band splitting due to an external field in the paramagnetic state, the spontaneous moment in the ordered state arises from the spontaneously spin-split bands caused in a simple mean field model by an effective exchange field $H_{\text{eff}} = Im$.

Introduction

Magnetic materials play a prominent role in modern technology. They are key components of motors, generators, and transformers. In this article, various magnetic materials of technological importance are described with an emphasis on recent developments.

Magnetic materials have a long history of usage. According to Chinese data, the compass was discovered in China more than 4500 years ago. There are also claims that a natural magnet was discovered in Magnesia (Asia Minor) more than 3500 years ago. Magnetic materials have contributed vitally to the history of civilization.

Traditionally, only those materials that exhibit ferromagnetic or ferrimagnetic properties are called “magnetic.” Only nine elements are ferromagnets. All are metals, of which three (Fe, Co, Ni) are iron-group metals and the other six (Gd, Tb, Dy, Ho, Er, Tm) are rare-earth metals. The transition metals Fe and Co are the basic elements for preparation of alloys and compounds with large Curie temperature (T_C) and a large spontaneous magnetization (M_s) (see Table 1). Some of the intermetallic compounds with rare-earth metals are characterized by a very high value of magnetocrystalline anisotropy and magnetostriction.

The primary criterion allowing for classification of magnetic materials is coercivity, which is a measure of stability of the remanent state. Soft magnetic materials are characterized by low values of coercivity ($H_c < 10^3 \text{ A m}^{-1}$), while the coercivity of hard magnetic materials (usually permanent magnets) is higher than 10^4 A m^{-1} . Finally, semihard magnetic materials (mostly storage media) have coercivities in between the above two values. In addition, there exist a number of sophisticated magnetic materials with unusual properties, such as giant magnetostriction, giant magnetoresistance, and giant magnetoimpedance. All these materials are important for modern technology and will be considered here. In modern applications, magnetic properties are tailored through precision tuning of the material microstructure. Thus, a central issue in the development and application of both soft and hard magnetic materials is the connection between extrinsic magnetic properties (coercivity, remanence, hysteresis loop) and microstructure. A universal relation was established between the coercivity H_c and the anisotropy constant K_1 :

$$H_c = 2\alpha K_1 / \mu_0 M_s - N_{\text{eff}} M_s \quad [1]$$

where the microstructural parameters α and N_{eff} describe the effects of microstructure and domain structure.

The present technology allows one to obtain a wide spectrum of microstructures ranging from amorphous, nanocrystalline to single crystals. The corresponding coercivities may vary by a factor of 10^7 to 10^8 from extremely soft to extremely hard magnetic materials.

Soft Magnetic Materials

Typical requirements for a soft magnetic material are low coercivity, high initial permeability, and low high-frequency losses. These characteristics usually go along with the following properties of the media:

- low effective magnetic anisotropy,
- high remanence,

Table 1 Magnetic properties of 3d and 4f magnetically ordered elements

Element	Curie temperature (K)	Saturation moment (μ_B)
Fe	1043	2.22
Co	1388	1.72
Ni	635	0.61
Gd	293	7.63
Tb	220	9.34
Dy	89	10.33
Ho	20	10.34
Er	20	9.1
Tm	32	7.14

- small magnetostriction (to suppress magnetoelastic contribution to the magnetic anisotropy), and
- low conductivity.

There was a remarkable progress in production and applications of soft magnetic materials in recent years. The static permeability, for example, has been increased to huge values in materials with near-zero values of magnetic anisotropy and magnetostriction. The best soft magnetic materials have permeabilities as large as $\mu > 10^5$. The permeability μ describes the response of magnetic materials to a weak magnetic field. For small fields, this response is linear and may be characterized by the initial permeability μ_i . Generally, the permeability is determined by two mechanisms: the growth of some magnetic domains at the expense of others (wall mechanism) and the rotation of magnetization within each domain (rotation mechanism). The same two mechanisms are also responsible for the hysteresis loop in soft magnetic materials. There are two classes of losses in these materials: hysteresis losses (determined by the area of hysteresis loop) and eddy current losses (related to the DC electrical resistivity). After a thermal demagnetization or after rapid changing of magnetization, almost all soft magnetic materials show a slow decrease of their permeability as a function of time (t), according to a law:

$$\delta\mu = -D \ln t \quad [2]$$

This decay of permeability with time is called “disaccommodation.” The disaccommodation is ascribed to an increase in the domain wall stiffness, which originates in the presence of mobile defects interacting with magnetization.

Iron and Soft Steels

Iron is a very good and relatively cheap soft magnetic material. It has a very high saturation magnetization at room temperature and a large Curie temperature (see Table 2). Pure iron or soft steels (low-carbon steels, silicon steels) are used in magnetic shielding, in power and distribution transformers, in small motors, in electromagnets, and in various electromechanical devices. In AC applications, low-carbon steels are used because of their high permeability and low core loss. Silicon steels are widely used in transformers, rotating power equipment, and relays. Silicon is added to pure iron to increase resistivity and permeability and to decrease magnetostriction and magnetocrystalline anisotropy. In silicon steels, the basic magnetostriction constants approach zero at a silicon level slightly greater than 6 wt.%. Such high silicon content alloys are usually produced by a fast solidification technique. This melt-spinning technique was initially developed for amorphous alloys. Silicon steels are divided into two main categories: Fe–Si sheets with nonoriented grain texture and grain-oriented Fe–Si sheets. In the latter case, a preferred crystallographic texture leads to a reduction of core loss and increase of permeability. Annealing of iron and steels removes stresses and improves the time stability of magnetic parameters. In order to avoid the $\alpha \rightarrow \gamma$ phase transition of iron the temperature of annealing should not exceed 1125 K. In the case of silicon steel, this temperature is even higher since silicon stabilizes the α -Fe phase.

Table 2 Soft magnetic materials (crystalline)

Material	Saturation induction B_s (T)	Coercivity H_c (A m^{-1})	Initial permeability μ_i
Iron (ingot)	2.14	80	150
Carbon steel	2.14	100	200
Silicon iron (3% Si)			
Unoriented	2.01	60	270
Oriented	2.01	7	1 400
Permalloy (79% Ni, 5% Mo)	0.80	1	40000
Permendur (49%Co, 2% V)	2.40	160	800
Supermendur (49%Co, 2% V)	2.40	16	1000
Alfenol (16%Al)	0.80	3.5	4000
MnZn ferrite	0.40	7	10000
NiZn ferrite	0.33	80	290

Nickel–Iron Alloys

Nickel–iron alloys (known as “permalloys”) are used for electronic transformers and inductor applications in the 1–100 kHz range. These are characterized by high initial permeability (see Table 2) and good ductility for forming into very thin strips. Fe–Ni alloys with 80% of Ni are characterized by the almost simultaneous vanishing of anisotropy and magnetostriction. The best alloys have the composition $\text{Fe}_{15}\text{Ni}_{80}\text{Mo}_5$. Alloys with very high permeability are mainly used in safety devices and in magnetic field shielding.

Iron–Cobalt Alloys

The most important iron–cobalt soft magnetic alloys are “Permendur” (49%Fe–49%Co–2%V) and “Supermendur” (see Table 2). The technological importance of these alloys is a consequence of their high saturation magnetization and high Curie temperature. They are characterized by high permeabilities and low coercivities. Because of high cobalt content, Fe–Co alloys are relatively costly and they are used only for special purposes where cost of the magnetic material is not of great importance, for example, in airborne medium-frequency electrical engineering and in high-temperature magnetic devices.

Soft Ferrites

The term “ferrite” refers to spinel ferrites with the general formula $\text{MO Fe}_2\text{O}_3$, where M is a divalent cation (e.g., Mg^{2+} , Zn^{2+} , Cd^{2+} , Mn^{2+} , Fe^{2+} , Co^{2+} , Cu^{2+}). The spinel structure is cubic, with a face-centered cubic oxygen anion lattice. Metallic ions are distributed between tetrahedral (a) and octahedral (d) sites. In the “normal spinel” structure, tetrahedral sites are occupied by divalent cations and the octahedral sites by trivalent cations. In the “inverse spinel” structure, the tetrahedral sites are occupied by trivalent cations while the octahedral sites are occupied by divalent and trivalent cations. Magnetism of ferrites is usually determined by antiferromagnetic interactions between magnetic cations located at octahedral and tetrahedral sites. It leads to a relatively low value of saturation magnetization. The Curie temperature in most ferrites is lower than that in metals. The anisotropy constant K_1 of soft ferrites is usually small and negative with the $\langle 111 \rangle$ axis being the easy magnetization direction. Additions of Fe^{2+} or Co^{2+} ions to the lattice provide positive contribution to K_1 and a tendency to change the easy magnetization direction (to $\langle 100 \rangle$ axis). It also gives a possibility to achieve a near-zero value of the anisotropy constant. The resistivity of ferrites is in the insulating range and much larger than that of metallic alloys. The dominant mechanism for the conduction in soft ferrites is the transfer of electrons between Fe^{2+} and Fe^{3+} ions on the octahedral sites. It means that resistivity of ferrites is dependent on the ferrous ions content. Resistivities of Mn–Zn ferrites range from 10^{-2} to $10\ \Omega\text{m}$, while Ni–Zn ferrites have resistivities $\sim 10^7\ \Omega\text{m}$. The hopping Fe^{2+} – Fe^{3+} also determines the frequency dependence of μ_i .

Ferrites have some disadvantages: low saturation magnetization (see Table 2), relatively low Curie temperature, and inferior mechanical properties. Despite these disadvantages, ferrites are widely used in modern technology. They are used in two main fields: power electronics (mainly Mn–Zn and Ni–Zn ferrites) and low-power techniques (Ni–Zn ferrites up to 300 MHz and Mn–Zn high-permeability ferrites up to some MHz).

Ferrimagnetic Iron Garnets

The basic formula of the ferrimagnetic rare-earth iron garnets is $\{\text{R}^{3+}\}_3[\text{Fe}_2^{3+}](\text{Fe}_3^{3+})\text{O}_{12}$, where R is either a rare-earth element or yttrium. These ions occupy dodecahedral {c} sites. The iron ions are distributed between tetrahedral (d) sites and octahedral [a] sites. Garnets crystallize in the cubic system. In a ferrimagnetic garnet, the magnetic moments of the octahedral and tetrahedral sublattices are antiparallel to each other. The moments of the Gd^{3+} and heavier R^{3+} ions couple antiferromagnetically to the net moment of the Fe^{3+} sublattices. The resulting magnetization of the garnet is the sum of these three contributions:

$$M(T) = |M_a(T) - M_d(T) + M_c(T)|$$

At low temperatures the rare-earth magnetization dominates. This effect is exactly canceled out by the net magnetization of iron sublattices at the “compensation temperature” T_{comp} . Below T_{comp} , the magnetization M_c lies parallel to a saturating field, and above T_{comp} it is antiparallel. The moments of the light rare-earth ions couple ferromagnetically to the net moment of the Fe^{3+} sublattices and no compensation points exist. In the compound $\text{Y}_3\text{Fe}_5\text{O}_{12}$ (YIG) the most attractive property is the extremely narrow ferrimagnetic resonance line width, of the order of $50\ \text{A m}^{-1}$. Thus, YIG with various partial substitutions for Y finds wide applications in microwave devices. Garnets find major application at lower frequencies ($< 5\ \text{GHz}$). Above 5 GHz, spinel ferrites are commonly used. YIG exhibits a room temperature saturation magnetization $\mu_0 M_s \approx 0.175\ \text{T}$ and a magnetocrystalline anisotropy $\sim 500\ \text{J m}^{-3}$. The saturation magnetization of light rare-earth garnets is slightly higher while it is much lower for heavy rare-earth garnets.

Amorphous Alloys

Amorphous alloys include two large classes: transition metal-metalloids with compositions near $(\text{Fe}, \text{Co}, \text{Ni})_{80}(\text{B}, \text{C}, \text{Si})_{20}$ and transition metals – Zr, Hf. The former type offers greater potential for technical applications. Amorphous alloys are produced mainly

by rapid ($\sim 10^6 \text{ K s}^{-1}$) quenching from the melt or by either sputtering or evaporation. The lack of long-range atomic order in amorphous magnetic alloys is responsible for: (1) high metallic resistivity ($\sim 10^{-6} \Omega \text{ m}$), (2) absence of macroscopic magnetocrystalline anisotropy, (3) absence of grain boundaries and dislocations playing the role of pinning centers in crystalline magnetic materials, (4) a broad range of compositions available, yielding a continuous spectrum of property values, (5) outstanding mechanical properties, and (6) excellent resistance to corrosion.

The first class of amorphous alloys is divided into three groups (see Table 3):

1. iron-based amorphous alloys with a saturation induction B_s in the 1.1–1.8 T range with excellent high-frequency (up to 100 kHz) characteristics,
2. iron–nickel based amorphous alloys with a relatively low saturation induction but at the same time a low magnetostriction, and
3. cobalt-based amorphous alloys with a near-zero magnetostriction, a very high permeability, and low losses.

In addition to the applications of Fe-based alloys in electric utility and industrial transformers, amorphous metals are increasingly used in power electronics, telecommunication equipment, sensing devices, electric power conditioning, electronic article surveillance systems, etc. Slow crystallization of materials with a high resistance to crystallization allows a decreased critical cooling and enables stable bulk metallic glass formation. In this way, Fe-based bulk amorphous alloys with good soft magnetic properties are fabricated.

In soft magnetic amorphous ribbons and wires, the “giant magnetoimpedance effect” (GMI) is observed. This effect consists of drastic changes of the complex impedance (both real and imaginary components) of amorphous alloys upon application of an external magnetic field (of a few Oe) or mechanical stresses. Sensitivity of up to 500% of relative impedance change per Oe is observed in the very low-field region. The GMI effect is strongly dependent on the frequency of the applied field and on the magnetic anisotropies present in the material. That makes GMI materials quite convenient for application in sensors of current, position, level of liquid, and pressure. The sensors are employed in technologies such as car traffic monitoring, quality control steels, detection of earthquakes, and medicine.

Nanocrystalline Alloys

Nanocrystalline alloys consist of homogeneously distributed ultrafine grains with an average size of $\sim 5\text{--}20 \text{ nm}$ embedded in an amorphous matrix. They are prepared from amorphous ribbons (with the addition of Cu and Nb), which are subjected to a recrystallization annealing. The volume ratio of the crystalline phase ranges from 50% to 80% and can be controlled by the annealing temperature. Nanocrystalline alloys present a lower coercivity field than the amorphous samples, higher initial permeability than the Co-based amorphous alloys (see Table 4), very low magnetostriction, and (due to the exchange softening) nearly zero effective magnetic anisotropy. The presence of Cu and Nb allows one to obtain well-differentiated microstructures. The resistivity of these materials is usually of the same order of magnitude as that of the amorphous ones, namely $1\text{--}1.5 \times 10^{-6} \Omega \text{ m}$. The high permeability and weak energy loss of soft nanocrystalline alloys make them valuable for various sensors, safety devices, high-frequency transformers, and in many other applications.

Table 3 Soft magnetic materials (amorphous)

Material	Curie temperature (K)	Saturation induction (T)	Coercivity (A m^{-1})	Magnetostriction constant (10^{-6})
$\text{Fe}_{81}\text{B}_{13.5}\text{Si}_{3.5}\text{C}_2$	370	1.61	3.2	30
$\text{Fe}_{67}\text{Co}_{18}\text{B}_{14}\text{Si}$	415	1.80	4.0	35
$\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_2\text{Nb}_8\text{B}_{20}$	508	0.71	1.7	10

$\text{Fe}_{78}\text{Si}_9\text{B}_{13}$	688	1.56	2.4	27

Hard Magnetic Materials

The most important hard magnetic materials suited for permanent magnets are expected to have the following intrinsic magnetic properties:

1. *High Curie temperature.* This favors the 3d elements which exhibit direct exchange.
2. *High saturation magnetization at room temperature.* This again favors 3d elements (Fe, Co). The 3d–4f intermetallics based on the light rare earth which couple parallel with the 3d moment, are of special interest here.
3. *High uniaxial anisotropy.* Uniaxial anisotropy is necessary for the formation of high coercivity. The main contribution to a reasonably high anisotropy comes from the 4f ions. This anisotropy is of the single-ion type. To combine the best features of 3d and 4f components, a strong 3d–4f coupling is required.

Permanent magnets are characterized by an extremely wide hysteresis loop. The most important extrinsic parameter is the coercivity, H_C , connected with the total anisotropy via eqn [1].

Alnicos

Alnicos are a group of heat-treated Fe–Co–Ni–Al–Cu alloys which can be divided into two main subgroups: isotropic alloys containing 0–20 wt.% Co (alnico 1–4) and anisotropic alloys with 22–24 wt.% Co and a titanium content of 5–8 wt.% (alnico 5–9). The anisotropy in case of alnicos 5–9 is produced by controlled cooling or isothermal heat treatment in a saturating magnetic field. The main source of anisotropy is the shape anisotropy associated with elongated Fe–Co particles in an Ni–Al matrix aligned parallel to the magnetic field during spinodal decomposition of the alloy. Alnicos are widely used as permanent magnets (see Table 5). The most important applications are loudspeakers, watt-hour meters, electric motors, generators, and alternators.

Hexagonal Ferrites

Hard ferrites have the general chemical formula $MFe_{12}O_{19}$, where M is Ba, Pb, or Sr. They have a hexagonal structure with Fe^{3+} ions located at five different crystallographic positions. The superexchange via bridging oxygen atoms leads to a collinear ferrimagnetic structure. The high magnetocrystalline anisotropy (see Table 6) has a crystal-field and dipolar origin. The intrinsic magnetic properties of hexagonal ferrites may be modified by chemical substitution. These ferrites exhibit a large coercivity (200–300 kA m^{−1}) but a relatively low remanence (~ 0.4 T). They are produced by ceramic techniques and are often bonded in plastic. Owing to their low price, hexagonal ferrites are widely used in electric motors in automotive and acoustic industries (electrical equipment for vehicles, starter motors, etc.).

Cobalt–Samarium Magnets

Hard magnets based on $SmCo_5$ possess the highest uniaxial anisotropies of any class of magnets ($K \sim 10^7$ J m^{−3}, see Table 7), while magnets based on Sm_2Co_{17} exhibit higher saturation magnetization and higher Curie temperature. Each of them has a uniaxial structure ($SmCo_5$ – hexagonal; Sm_2Co_{17} – hexagonal or rhombohedral). Chemical substitution in both compounds modifies their intrinsic and extrinsic magnetic properties. A small substitution of Cu for Co leads to precipitations of a nonmagnetic phase, which increases the coercivity. In this case, the coercivity mechanism is controlled by domain wall pinning on small $SmCo_5$ particles. A similar mechanism exists in $Sm_2(Co,Cu)_{17}$. The nucleation-controlled coercive force dominates in single-phase $SmCo_5$. The defects,

Table 5 Magnetic properties of alnicos

Alloys	Saturation induction (T)	Coercivity (A m ^{−1})	Energy product (BH) _{max} (kJ m ^{−3})
Alnico 3	0.5–0.6	54–40	10
Alnico 5	1.2–1.3	52–46	40–44
Alnico 7	0.74	85	24

Compound	Curie temperature (K)	Saturation magnetization (T)	Coercive field (kA m ⁻¹)	Anisotropy constant (MJ m ⁻³)	Energy product (kJ m ⁻³)
SmCo ₅	1020	1.07	1500	17.2	160
Sm ₂ Co ₁₇	1190	1.22	1100	3.3	260

Table 8 Magnetic properties of neodymium–iron–boron

	Curie temperature (K)	Saturation magnetization (T)	Coercive field (kA m ⁻¹)	Anisotropy constant (MJ m ⁻³)	Energy product (kJ m ⁻³)
Nd ₂ Fe ₁₄ B	585	1.52		4.5	
Magnet (standard)			1000		260
Magnet (high remanence)			1250		400

which act as nucleation centers, are mostly associated with the surface of milled powder particles. The Curie temperature and saturation magnetization of Sm₂Co₁₇ are substantially improved by partial Fe, Zr, and Cu substitution for Co. Fe is added to increase remanence, and Cu and Zr to form the required microstructure. In this case, the coercivity has a pinning-type character.

Neodymium–Iron–Boron Alloys

Permanent magnets based on Nd₂Fe₁₄B have record values for the energy product (BH)_{max}. Except for the relatively low Curie temperature, the Nd–Fe–B magnets are superior to all other magnetic materials. The Nd₂Fe₁₄B compound has a tetragonal structure. The Nd and Fe sublattices are aligned parallel to one another, giving a room temperature magnetization of 1.61 T, the largest of any rare-earth compound used for permanent magnets. The strong magnetocrystalline anisotropy of Nd₂Fe₁₄B (see Table 8) results from the low symmetry of both the Nd and Fe sites. All components of Nd₂Fe₁₄B can be partly substituted by metals or metalloids. Such substitution may lead to an improvement in the thermal stability of the magnetic properties above room temperature or/and to an improvement of the microstructure and performance of the magnet. For example, cobalt substitution improves the performance of Nd₂Fe₁₄B by an increase of the Curie temperature, but at the same time the presence of cobalt decreases the magnetocrystalline anisotropy.

Small quantities of Dy are often substituted for Nd to improve the coercivity of Nd–Fe–B magnets. However, dysprosium reduces the magnetization of the system. Two principal fabrication routes for Nd–Fe–B magnets are: powder metallurgy (for oriented sintered magnets) and melt spinning (used mostly for bonded magnets). The optimum composition for sintered magnets was found to be Nd₁₅Fe₇₇B₈ which is both Nd- and B-rich with respect to the stoichiometric Nd₂Fe₁₄B. The ideal two-phase microstructure in Nd–Fe–B sintered magnets consists of fully aligned grains of Nd₂Fe₁₄B separated by the minimum amount of a nonmagnetic intergranular phase. Coercivity of sintered magnets is dominated by the nucleation mechanism. High remanence-oriented magnets have energy product of ~400 kJ m⁻³ and a remanence approaching 1.5 T. A different microstructure and magnetization is encountered in nanocrystalline Nd–Fe–B magnets produced by melt spinning. The origin of coercivity in melt-spun Nd–Fe–B magnets is similar to that established for sintered magnets. The nanocrystalline structure of Nd–Fe–B magnets may also be developed by mechanical alloying. Milling Fe, Nd, and B to form Nd₂Fe₁₄B results in formation of α -Fe (of ~5 nm size) and an Nd-rich amorphous phase which should be heat treated to obtain high-coercivity material. A typical composition of these magnets is Nd₁₄Fe₈₀B₆. In case of fully dense isotropic nanomagnets, the characteristic energy products are ~100 kJ m⁻³ while the values of remanences are ~0.80 T. Mechanical alloying has also been used to synthesize other nanoscale two-phase mixtures of hard and soft magnetic phases. The exchange coupling between magnetically hard and soft phases can result in significant enhancement of the remanence. These nanocomposites are known as “exchange spring magnets.” For this mechanism to be effective, the size of the soft grains should not exceed a few times the domain wall width for the hard phase (~20–30 nm). In such cases, the material behaves as if it were homogeneous, with anisotropy and magnetization being equal to the mean value of the constituent phases. Some typical examples are Nd₂Fe₁₄B/Fe₃B, Nd₂Fe₁₄B/Fe, and Sm₂Fe₁₇N₃/Fe.

Despite their relatively low Curie temperature and their susceptibility to corrosion, Nd–Fe–B magnets have found a great number of applications where high coercivity and energy result in design advantages. The applications include voice coil motors of hard disk drives and other small compact electronic products.

Giant Magnetostrictive Materials

Rare-earth metals have intrinsically huge magnetostriction because of the strong 4f electrons’–crystal lattice coupling. Although this coupling is indirect, it is huge because of the large spin–orbit coupling and the highly anisotropic localized nature of the 4f electrons. The relatively low magnetic ordering temperatures of rare-earth metals (R) (see Table 1) make use of the high value

Table 9 Magnetostriction constants for several rare-earth materials

Material	$T = 4.2\text{ K}$	Room temperature	
	$\lambda_{111} (10^{-6})$	$\lambda_{111} (10^{-6})$	Polycrystal (10^{-6})
TbFe ₂	4400	2600	1750
Tb _{0.3} Dy _{0.7} Fe ₂		1600	1200
Polymer-bonded Terfenol-D			536
Tb ₃ Fe ₅ O ₁₂ garnet	2460		

of magnetostriction at room temperature, possible only by combining them with 3d metals. Such a combination was realized most effectively in the Laves phase compound RFe₂, particularly in TbFe₂ (see Table 9), also known as “Terfenol.” However, this compound has an intrinsically large magnetocrystalline anisotropy which limits its technical application. By addition of Dy atoms with a positive magnetocrystalline anisotropy, it is possible to compensate the negative magnetocrystalline anisotropy of terbium. The compound Tb_{0.3}Dy_{0.7}Fe₂ known as “Terfenol-D” maintains a giant magnetostriction (at low magnetic fields) with low magnetocrystalline anisotropy and relatively high Curie temperature. In the polycrystalline state, giant magnetostriction is possible only when the grains are aligned along the easy $\langle 111 \rangle$ direction and the effect is measured along this direction. This is because Terfenol-D alloys exhibit enormously large anisotropy in magnetostriction $\lambda_{111} > \lambda_{100}$. These alloys are produced either by a directional solidification method, sintering, or by a polymer bonding. The last method has an advantage over the other two because including the polymer binder with a high electrical resistivity, the frequency limit of the polymer-bonded composites can be extended to hundreds of kHz. Favorable magnetostrictive properties are also observed in amorphous R-Fe alloys. The main industrial applications of “Terfenol-D” are linear actuators.

Manganites

Doped perovskite manganites La_{1-x}A_xMnO₃ (where A is Ba, Ca, Sr, or Pb) show a wide variety of magnetic field-induced phenomena, including the gigantic decrease of resistance under the application of a magnetic field. It is termed “colossal magnetoresistance effect (CMR).” By replacement of a trivalent rare earth by a divalent alkaline earth, the nominal valence of Mn can be continuously tuned between 3+ (for $x=0$) and 4+ (for $x=1$). The magnetic and magneto-transport properties of manganites are governed mainly by the mixed valence Mn³⁺/Mn⁴⁺ ions and less affected by the oxygen ions. The d-electrons are subject to a variety of interactions, of which the most important are the double exchange, superexchange, and Jahn–Teller coupling. The double exchange interaction is responsible for a strong correlation between magnetization and resistivity (or magnetoresistivity). The large resistance is related to the formation of small lattice polarons in the paramagnetic state. In these interactions, an important role is played by the e_g electrons on the Mn³⁺ ions. The orbital degeneracy leads to a variety of instabilities (such as magnetic, structural, and metal–insulator transitions, collapse of charge-ordered states under a magnetic field) and is responsible for a strong magnetoelastic coupling. The e_g electrons can be itinerant and hence play the role of conduction electrons, when electron vacancies or holes are created in the e_g orbital states of the crystal. The other characteristic feature of manganites is the appearance of unusual collective state of charge order, observed mostly for $x>0.3$. This insulating state competes with two other basic phases in manganites, namely with the ferromagnetic metallic phase and the nonmetallic paramagnetic phase. A number of experiments have demonstrated that over wide ranges of compositions there can be a coexistence between the ferromagnetic metallic and charge-ordered insulating phases.

Introduction

The word “magnetocaloric” is derived from Greek *Magnes (lithos)* (literally, stone of Magnesia, ancient city in Asia Minor), that is, magnesian (stone) or “magnetite” that has been known for thousands of years to attract articles made from iron, and Latin “calor” for heat, which evolved into French “calorique” – the name of the invisible and indestructible fluid that, according to a theory prevailing in 1700s, was thought to be responsible for virtually everything related to heat. This two-part word describes one of the most fundamental physical properties of magnetic materials: that is, when a solid is exposed to a varying magnetic field, its temperature may be measurably increased or decreased with both the sign and the magnitude of the temperature difference between the final and the initial states of the material dependent on numerous intrinsic and extrinsic factors. The chemical composition, crystal structure, and magnetic state of a compound are among the most important intrinsic material parameters. The temperature, surrounding pressure, and sign of the magnetic field change are examples of extrinsic variables that affect these magnetic-field-induced temperature changes and, therefore, play a role in defining the magnetocaloric effect (MCE).

Inherent to every magnetic solid, the magnetocaloric effect has exceptional fundamental importance because it covers length, energy, and timescales spanning over many orders of magnitude: from quantum mechanics to micromagnetics, from statistical to macroscopic thermodynamics, and from spin dynamics to bulk heat flow and thermal conductivity. Mapping out this vast landscape is an enormously challenging task, yet even partial successes along the way facilitate a better understanding of how to design novel magnetic solids; in other words, they help in creating an environment in which a material could be tailored to exhibit a certain combination of magnetic and thermal properties. In addition to its basic significance, the magnetocaloric effect is the foundation of near-room-temperature magnetic refrigeration, which is poised for commercialization in the foreseeable future and may soon become an energy-efficient and environmentally friendly alternative to vapor-compression refrigeration technology. Practical applications of the magnetocaloric effect, therefore, have the potential to reduce the global energy consumption, and eliminate or minimize the need for ozone depleting, greenhouse, and hazardous chemicals.

Discovery and First Application of the Magnetocaloric Effect

MCE was originally discovered in iron by E Warburg, who reported the phenomenon in 1881. The nature of the MCE was explained and its usefulness to reach temperatures below 1 K by adiabatically demagnetizing a paramagnetic substance was suggested independently in the mid-1920s by P Debye and W F Giauque. Namely, after cooling a paramagnetic material in a large magnetic field to as low a temperature as possible by conventional means, such as pumping on liquid helium, the material was to be thermally isolated from its surroundings, the magnetic field removed, and the sample was predicted to cool well below 1 K due to the magnetocaloric effect.

Together with his student D P MacDougall, W F Giauque was the first to verify this prediction experimentally. As Giauque and MacDougall wrote in their 12 April 1933 letter to the editor of the *Physical Review*, “On March 19, starting at a temperature of about 3.4 K, the material cooled to 0.53 K. On April 8, starting at ~ 2 K, a temperature of 0.34 K was reached. On April 9, starting at ~ 1.5 K, a temperature of 0.25 K was attained.” They achieved these breakthroughs by using 61 g of hydrated gadolinium sulfate, $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, and by reducing the magnetic field from 0.8 to 0 T. Giauque and MacDougall conclude their short (about 200 words) letter that was published in 1 May 1933 issue of the *Physical Review* with the following statement: “It is apparent that it will be possible to obtain much lower temperatures, especially when successive demagnetizations are utilized.” This technique is known as adiabatic demagnetization refrigeration and it is successfully employed today in ultra-low-temperature research – for example, nuclear adiabatic demagnetization has been and is being used to reach micro-kelvin temperatures.

Fundamentals of the Magnetocaloric Effect

The MCE occurs due to the coupling of a magnetic sublattice with an external magnetic field, which affects the magnetic part of the total entropy of a solid. Similar to isothermal compression of a gas during which positional disorder and, therefore, the corresponding component of the entropy of a system are suppressed, isothermal magnetizing of a paramagnet near the absolute zero temperature or a ferromagnet near its spontaneous magnetic ordering temperature – the Curie temperature, T_C – greatly reduces disorder of a spin system, thus substantially lowering the magnetic part of the total entropy. In a reversible process, which resembles the expansion of a gas at constant temperature, isothermal demagnetization restores the zero field magnetic entropy of a system. The MCE, therefore, can be measured as an extensive thermodynamic quantity – the isothermal magnetic entropy change, ΔS_M , which is illustrated in Figure 1 as a difference between the two entropy functions taken at the same temperature and is marked by a vertical arrow.

When a gas is compressed adiabatically, its total entropy remains constant whereas velocities of the constituent molecules, and therefore, the temperature of the gas both increase. Likewise, the sum of the lattice and electronic entropies of a solid must be changed by $-\Delta S_M$ as a result of adiabatically magnetizing (or demagnetizing) the material, thus resulting in an increase (decrease) of the lattice vibrations and the adiabatic temperature change, ΔT_{ad} , which is an intensive thermodynamic quantity also used to measure and express the MCE. In Figure 1, ΔT_{ad} is illustrated as a difference between the two entropy functions taken at the same entropy and is indicated using a horizontal arrow. It is worth noting that in the case of a gas, it is a “change of pressure” that results either in the adiabatic temperature rise or drop, or the isothermal entropy change, while in the case of a magnetic solid it is a “change of the magnetic field” that brings about the MCE. Needless to say, no matter how strong the magnetic field around the sample, the MCE will remain zero as long as the field is kept constant.

For a given material at a constant pressure, the two quantitative characteristics of the magnetocaloric effect are functions of the absolute temperature (T) and the magnetic field change ($\Delta B = B_f - B_i$), where B_f and B_i are the final and initial magnetic fields, respectively, experienced by the material. The MCE can be easily computed provided the behavior of the total entropy (S) of a compound is known as a function of temperature in both the initial and final magnetic fields, e.g., see Figure 1:

$$\Delta S_M(T, \Delta B)_{\Delta B=B_f-B_i} = S(T, B)_{B=B_f} - S(T, B)_{B=B_i} \quad [1]$$

$$\Delta T_{ad}(T, \Delta B)_{\Delta B=B_f-B_i} = T(S, B)_{B=B_f} - T(S, B)_{B=B_i} \quad [2]$$

Equation [2], in which the entropy is the independent variable and the temperature is the dependent variable, is straightforwardly employed in direct measurements of ΔT_{ad} . Thus, the temperature of a sample is measured in both B_i and B_f , that is, before and after the magnetic field has been altered. The difference between the two temperatures yields the intensive MCE value, which is usually reported as a function of temperature for $B_i = 0$.

At equilibrium, both ΔS_M and ΔT_{ad} are correlated with the magnetization (M), magnetic flux density (B), heat capacity at constant pressure (C), and absolute temperature by one of the following fundamental Maxwell equations:

$$\Delta S_M(T, \Delta B)_{\Delta B=B_f-B_i} = \int_{B_i}^{B_f} \left(\frac{\partial M(T, B)}{\partial T} \right)_B dB \quad [3]$$

$$\Delta T_{ad}(T, \Delta B)_{\Delta B=B_f-B_i} = - \int_{B_i}^{B_f} \left(\frac{T}{C(T, B)} \times \frac{\partial M(T, B)}{\partial T} \right)_B dB \quad [4]$$

Figure 1 The total entropy of gadolinium in the vicinity of $T_C=294$ K in 0 and 7.5 T magnetic fields. The data are for a high-purity single crystalline Gd with the magnetic field vector parallel to the [0001] crystallographic direction of the specimen. The vertical arrow illustrates ΔS_M ; the horizontal arrow represents ΔT_{ad} .

Figure 2 The extensive, ΔS_M , and intensive, ΔT_{ad} , MCE of the elemental Gd in the vicinity of its Curie temperature, $T_C=294$ K, for a magnetic field change from 0 to 7.5 T. The data are for a high-purity single crystalline Gd with the magnetic field vector parallel to the [0001] crystallographic direction of the specimen.

As immediately follows from eqns [1]–[4], materials whose total entropy is strongly influenced by a magnetic field and where the magnetization varies rapidly with temperature, are expected to exhibit an enhanced MCE. The latter peaks when $|(\partial M(T, B)/\partial T)_B|$ is the greatest, that is, around the T_C in a conventional ferromagnet or near the absolute zero temperature in a paramagnet. Usually, the MCE of a simple ferromagnet is gradually lowered both below and above the T_C , as is clearly seen in Figure 2.

Equations [3] and [4] are easily derived from general thermodynamics, yet both fail to describe the MCE in the vicinity of a truly discontinuous first-order phase transition when either or both $|(\partial M(T, B)/\partial T)_B|$ and $[T/C(T, B)]_B$ do not exist even if the phase volume change is negligibly small. (By definition, partial first derivatives of Gibbs free energy with respect to intensive thermodynamic variables, for example, T , P , or B , vary discontinuously at the first-order phase transition. As a result, the bulk magnetization is expected to undergo a discontinuous change at constant temperature; and the heat capacity is expected to be infinite during a first-order phase transformation. Thus, in theory, $[\partial M(T, B)/\partial T]_B$ and $[T/C(T, B)]_B$ do not exist at the temperature of the first-order transition. In reality, these changes occur over a few-kelvin-wide temperature range and both functions can be measured experimentally.) Equations [1] and [2], on the other hand, define the MCE regardless of the thermodynamic nature of the phase transformation that occurs, if any, in a material.

For a first-order phase transition, it is also possible to employ an approximation, which is based on the Clausius–Clapeyron equation:

$$\left(\frac{dB}{dT}\right)_{eq} = \left(\frac{\Delta S}{\Delta M}\right)_T \quad [5]$$

In eqn [5], the left-hand-side derivative is taken under equilibrium conditions, that is, when Gibbs free energies of the two phases are identical to one another. For the right-hand side, $\Delta S = S_2 - S_1$ and $\Delta M = M_2 - M_1$, where the subscripts 1 and 2 correspond to the states of the material in the initial and final magnetic fields, respectively. Obviously, eqn [5] is only applicable when B_f is strong enough to complete the transformation from a state 1 to state 2 and when the quantity dB/dT at equilibrium is known. In other words, the B – T phase diagram for the system must be well established. By using the Clausius–Clapeyron equation, only an estimate of the extensive MCE, $\Delta S_M = \Delta S$, is possible.

Magnetic Order and the Magnetocaloric Effect

It is easy to see (Eqns [3] and [4]) that both ΔS_M and ΔT_{ad} are proportional to the derivative of bulk magnetization with respect to temperature at constant magnetic field. The ΔT_{ad} is also proportional to the absolute temperature and inversely proportional to the heat capacity at constant magnetic field. It is predictable, therefore, that any material should have the largest MCE when its magnetization is changing most rapidly with temperature. This, for example, occurs in the vicinity of a Curie temperature of a ferromagnet. (From eqn [4] it is not obvious that $\Delta T_{ad}(T)_{\Delta B}$ is at its maximum at the Curie temperature because heat capacity of a material ordering ferromagnetically also peaks around T_C . It can be shown, however, that the maximum of $\Delta T_{ad}(T)_{\Delta B}$ does indeed occur in the immediate vicinity of T_C , especially when $B_i=0$ and $\Delta B \rightarrow 0$. By directly measuring $\Delta T_{ad}(T)_{\Delta B}$ in low magnetic fields, it is, therefore, possible to determine the Curie temperature of a ferromagnet.) The MCE will decrease below T_C , where the magnetization

approaches saturation and becomes weakly dependent on temperature, and above the Curie temperature when the magnetization shows only a paramagnetic response, that is, it is proportional to T^{-1} , while its derivative maintains a proportionality to T^{-2} .

Conventional ferromagnets, therefore, typically display “caret-like MCE.” This kind of behavior is easily recognizable in Figure 2, and it is also shown in Figure 3a for a $\text{Gd}_5\text{Si}_{2.5}\text{Ge}_{1.5}$ compound. The latter orders ferromagnetically via a second-order phase transformation at 312 K. As the ΔB increases, the magnitude of the MCE of a conventional ferromagnet also increases. The rate of change of the MCE with magnetic field, that is, the instantaneous derivative of the MCE with respect to ΔB is, however, the largest at the lowest B_f . The intensive measure of the MCE can vary from a fraction of 1 K T^{-1} to several K T^{-1} . Elemental Gd, for example, exhibits a $d[\Delta T(T, \Delta B)]/d(\Delta B)$ of $\sim 3 \text{ K T}^{-1}$ around T_C when B_f is on the order of 1 T. The derivative falls to $\sim 1.8 \text{ K T}^{-1}$ when B_f approaches 10 T. It is worth noting that away from absolute zero, $d[\Delta T(T, \Delta B)]/d(\Delta B)$ in conventional ferromagnetic materials is only weakly dependent on temperature (see Figure 3a).

Anomalous behaviors of the MCE are closely related to anomalous changes in the magnetic structures of solids causing unusual behaviors of the two functions, $[\partial M(T, B)/\partial T]_B$ and $[T/C(T, B)]_B$, which are carried over to both $\Delta S_M(T)_{\Delta B}$ and $\Delta T_{ad}(T)_{\Delta B}$ (see eqns [3] and [4]). One of the most commonly observed MCE anomalies is when a material undergoes two or more successive magnetic transitions in close proximity to one another. Then, instead of a conventional caret-like shape, a skewed caret, sometimes approaching a flat and an almost constant value as a function of temperature, that is, a “table-like MCE” can be observed. An example of such behavior is shown in Figure 3b for $\text{Gd}_{0.54}\text{Er}_{0.46}\text{AlNi}$. Both $\Delta S_M(T)_{\Delta B}$ (Figure 3b) and $\Delta T_{ad}(T)_{\Delta H}$ (not shown) of this material are almost constant between the two successive magnetic phase transition temperatures, which are $\sim 20 \text{ K}$ apart. Anomalous MCE behaviors may also be due to low-lying crystalline electric fields and strong quadrupolar and/or

Figure 3 Normalized magnetocaloric effect of (a) $\text{Gd}_5\text{Si}_{2.5}\text{Ge}_{1.5}$ ($T_C=312 \text{ K}$), (b) $\text{Gd}_{0.54}\text{Er}_{0.46}\text{AlNi}$ ($T_C=14.5 \text{ K}$ (the normalization temperature) and 35 K) and (c) $\text{Gd}_5\text{Si}_2\text{Ge}_2$ ($T_C=273 \text{ K}$) shown as a function of the reduced temperature for various magnetic field changes. In all cases, $B_i=0$. The $\Delta S_M(\text{max})$ values are 1.57 J g^{-1} , 0.63 J g^{-1} , and 2.61 J g^{-1} at $\Delta B=10 \text{ T}$ for $\text{Gd}_5\text{Si}_{2.5}\text{Ge}_{1.5}$, $\text{Gd}_{0.54}\text{Er}_{0.46}\text{AlNi}$, and $\text{Gd}_5\text{Si}_2\text{Ge}_2$, respectively.

magnetoelastic interactions. Furthermore, the MCE can be adjusted over a broad range of behaviors by mixing two or more individual compounds or phases, each with a simple caret-like MCE, into a composite where the resulting isothermal magnetic entropy change will be a weighted sum of the corresponding values of the individual components.

Generally, a more complicated magnetic behavior results in an anomalous and a more complicated behavior of the MCE. For instance, upon cooling in a zero magnetic field, elemental Dy orders antiferromagnetically at ~ 180 K with a helical magnetic structure, and then transforms from the helical antiferromagnetic state to a ferromagnet at ~ 90 K. When the magnetic field is between 0 and ~ 2 T, a few additional magnetic structures emerge in pure Dy between 90 and 180 K. Thus, when the magnetic field is low, the MCE of Dy shows a sharp step-like increase at ~ 90 K due to a first-order ferromagnetic–antiferromagnetic transition, and then goes through a minimum immediately followed by a weak maximum at ~ 180 K for $\Delta B = 1$ T (see Figure 4). The minimum exists because the application of a magnetic field to an antiferromagnet increases the magnetic entropy, thus inverting the sign of the MCE (in a ferromagnet the increasing field decreases magnetic entropy). When B_f is increased to 2 T, the magnetic field is strong enough to quench the first-order ferromagnetic–antiferromagnetic phase transition and it induces a noncollinear magnetic structure which yields a broad MCE maximum at ~ 127 K. Since a 2 T magnetic field is not strong enough to destroy this noncollinear structure, the slightly negative ΔT_{ad} is still observed at ~ 174 K. The latter is followed by a weak caret-type peak at ~ 181 K (Figure 4). Upon increasing the magnetic field to 5 T, it becomes strong enough to suppress all of the magnetic structures except the ferromagnetic phase and the MCE of Dy for $\Delta B = 5$ T has a single, somewhat skewed, caret-type peak at ~ 181 K.

Most magnetic materials on cooling undergo a second-order phase transition from a paramagnet to a ferromagnet with a conventional MCE behavior (Figures 2 and 3a), or from a paramagnet to an antiferromagnet with a skewed caret-like MCE if the magnetic field is large enough to destroy the antiferromagnetism and cause it to change to a ferromagnetic structure (Figure 4). A few materials, however, form a ferromagnetically ordered phase through a first-order magnetic phase transition, which may also be coupled with a change of the crystal lattice. One such example is illustrated in Figure 3c. Here, since the phase transition in $\text{Gd}_5\text{Si}_2\text{Ge}_2$ is of the first order, the $|\partial M(T, B)/\partial T|_B$ is larger than usual (but not infinite and undefined as could happen if the transition occurs infinitely fast at constant temperature, pressure, and magnetic field), and therefore, the MCE is also larger than usual (see eqns [3] and [4]). Technically, this behavior is known as the “giant MCE.” If one compares the behavior of the giant MCE in $\text{Gd}_5\text{Si}_2\text{Ge}_2$ with that of the other two materials shown in Figures 3a and 3b the most obvious difference is that at large magnetic fields the MCE versus temperature is extended considerably toward the high-temperature side of the peak, but the increase in the magnitude of the MCE with increasing field is affected to a much lesser extent than that in second-order phase transition compounds.

The MCE in first-order phase transition materials undergoing coupled magnetostructural transformations may be further enhanced by the added difference of the entropies of the two crystallographic modifications of the material, $\Delta S_{st} = \pm(S_{HF} - S_{LF})$, where HF and LF designate the high field and the low field phases, respectively:

$$\Delta S_M(T, \Delta B)_{\Delta B=B_f-B_i} = \int_{B_i}^{B_f} \left(\frac{\partial M(T, B)}{\partial T} \right)_B dB + \Delta S_{st} \quad [6]$$

It is worth noting that unlike the first factor of the right-hand side of eqn [6], which represents the conventional contribution to the isothermal magnetic entropy change (see eqn [3]), ΔS_{st} is magnetic field independent provided the change from B_i to B_f is large enough to complete the structural transformation.

Although the last factor in eqn [6] is a hidden parameter in conventional measurements of the MCE, an estimate based on comparing the MCE exhibited by the closely related materials with and without magnetic field-induced structural transformations indicates that ΔS_{st} may account for more than a half of the total magnetic entropy change in magnetic fields below 5 T. Advanced magnetocaloric materials should, therefore, exist in solid systems where extensive structural changes are coupled with ferromagnetic

Figure 4 The magnetocaloric effect in ultrapure Dy calculated from the heat capacity data.

ordering, and therefore, can be triggered by a magnetic field. Considering eqn [6], the strongest MCE should be found in novel compounds engineered in order to maximize the entropy of a structural transformation, ΔS_{st} . An extensive listing of ΔS_M and ΔT_{ad} values can be found in the reviews by Gschneidner and Pecharsky, and Tishin and Spichkin – see the “Further reading” section.

Active Magnetic Regenerator Cycle and Near-Room-Temperature Magnetic Refrigeration

Adiabatic demagnetization refrigeration, described at the beginning of this article, is a discontinuous process for all practical reasons because it may take as much as a few hours to repeat the refrigeration cycle and reach the target temperature. The history of continuous magnetic refrigeration can be traced to the work of S C Collins and F J Zimmerman, and C V Heer, C B Barnes and J C Daunt, who in the early 1950s built and tested two magnetic refrigerators operating between ~ 1 and 0.2 K by periodically magnetizing and demagnetizing iron ammonium alum. The apparatus built by Heer, Barnes, and Daunt operated at 1/120 Hz frequency (2 min per cycle) and on average extracted $12.3 \mu\text{J s}^{-1}$ from the cold reservoir at 0.2 K.

It was not, however, until 1976 when G V Brown reported a near-room-temperature continuously operating magnetic refrigerator, that it became clear that magnetic refrigeration may be successfully utilized at significantly higher temperatures and achieve much larger temperature spans than the maximum observed MCE. Brown was able to attain a 47 K no-load temperature difference between the hot end (319 K) and cold end (272 K) of his unit by regenerating a column of fluid using Gd metal and a magnetic field change from 0 to 7 T and from 7 to 0 T. The achieved temperature difference was more than three times the MCE of Gd for $\Delta B = 7$ T (see Figure 2, where for a slightly greater $\Delta B = 7.5$ T, the maximum ΔT_{ad} of Gd is around 16 K at $T_C = 294$ K; the MCE is ~ 13 K and ~ 11 K at 319 K and 272 K, respectively).

Following the early work of Brown, the concept of active magnetic regenerator (AMR) refrigeration was introduced by W A Steyert in 1978 and developed by J A Barclay and W A Steyert in the early 1980s. It was subsequently brought to life in the later 1990s, when various magnetic refrigeration units were built in the US, Europe, and Japan. In the AMR cycle, shown schematically in Figure 5, a porous bed of a magnetic refrigerant material acts as both the refrigerant that produces refrigeration (i.e., temperature lift) and the regenerator for the heat transfer fluid. Assume that the bed is at a steady state with the hot heat exchanger at 18°C and the cold heat exchanger at 2°C . In Figure 5a, the initial temperature profile for the bed is in its demagnetized state in zero magnetic field (dashed line). When a magnetic field is applied to the refrigerant, each particle in the bed warms because of the MCE to form the final magnetized bed temperature profile (solid line). The amount each particle warms is equal to ΔT_{ad} reduced by the effect of the heat capacity of the heat transfer fluid in the pores between the particles. Next, the 2°C fluid flows through the bed from the cold end to the hot end (Figure 5b). The bed is cooled by the fluid, lowering the temperature profile across the bed (from the dashed line to the solid line), and the fluid in turn is warmed by the bed, emerging at a temperature close to the temperature of the bed at the warm end. This temperature is higher than 18°C , so heat is removed from the fluid at the hot heat sink as the fluid flows through the hot heat exchanger. After the fluid flow is stopped, the magnetic field is removed, cooling the bed by the MCE (from the dashed line to the solid line in Figure 5c). The refrigeration cycle is completed by forcing the 18°C fluid to flow from the hot to the cold end of the bed (Figure 5d). The fluid is cooled by the bed, emerging at a temperature below 2°C and removes heat from the cold sink as the fluid passes through the cold heat exchanger. After completion of this last step, the cycle is repeated beginning from step (a) (Figure 5).

Figure 5 The four steps of the active magnetic regenerator cycle: magnetizing (a), flow from the cold heat exchanger (CHEX) to the hot heat exchanger (HHEX) (b), demagnetizing (c), and flow from HHEX to CHEX (d). This description follows that introduced by C B Zimm and A J DeGregoria in 1993.

The AMR cycle outlined above has several positive features useful for practical application in magnetic refrigeration devices. First, the temperature span of a single stage can greatly exceed that of the MCE of the magnetic refrigerant because the MCEs of the individual particles collectively change the entire temperature profile across the bed. Second, because the bed acts as its own regenerator, heat need not be transferred between two separate solid assemblies, but rather between the solid particles in a single bed via the action of a fluid. Third, the individual particles in the bed do not encounter the entire temperature span of the stage, and hence the bed may be made into layers, each containing a magnetic material with properties optimized for a particular temperature range.

The AMR refrigeration cycle has been successfully realized in a laboratory prototype magnetic refrigerator, which was recently designed and constructed by the Astronautics Corporation of America. The device is shown together with its schematic diagram in Figure 6. The refrigerator operates near room temperature in a magnetic field between 0 and ~ 1.5 T created by a permanent magnet. As the wheel spins, it brings one of its sections containing the magnetic refrigerant (the regenerator bed) into the high magnetic field volume, where the bed is heated due to the MCE (see Figure 6a). As long as this section of the wheel moves between the poles of the permanent magnet, it remains in the magnetized state and the heat exchange fluid (water) flows from the cold heat exchanger through the bed and into the hot heat exchanger. This corresponds to the second step of the AMR cycle shown in Figure 5b. While the wheel continues to spin, the same section exits from the high magnetic field volume. As the bed cools due to the MCE, the heat exchange fluid flow is reversed and it now flows from the hot heat exchanger through the bed toward the cold heat exchanger, thus completing steps (c) and (d) of the AMR cycle illustrated in Figure 5.

This permanent magnet-based rotating bed magnetic refrigerator was recently awarded US patent no. 6 526 759. The unit can operate at frequencies exceeding 1 Hz and it has achieved a maximum cooling power of 95 W and a maximum temperature span of 20°C . As tested by engineers at the Astronautics Corporation of America, the Carnot efficiency of this laboratory prototype system

Figure 6 (a) The principal schematic diagram of the device and (b) laboratory prototype magnetic refrigerator designed and constructed by the Astronautics Corporation of America in 2001. A ~ 1.5 T magnetic field around the wheel filled with Gd spheres is produced by a permanent magnet. The refrigerator operates at ambient conditions with a maximum temperature span of $\sim 20^\circ\text{C}$ and maximum cooling power of 95 W. compares favorably with conventional vapor-cycle refrigeration devices, thus making magnetic refrigeration the first energy-efficient solid-state refrigeration technology.

The Future of the Magnetocaloric Effect

Considering practical applications of the MCE, its extent is one of the most critical parameters defining the performance of a magnetic refrigerator – the stronger the MCE the higher the efficiency of the device, all other things being equal. As is often the case with emerging technologies, numerous applications of magnetic refrigeration may stem from a reliable foundation formed by advanced magnetocaloric materials. For example, the availability of low-cost high-performance solids exhibiting enhanced MCE between ~ 250 and ~ 350 K is an important requirement in order to facilitate commercialization of magnetic refrigeration for a variety of consumer uses – from home appliances to climate control in motor vehicles. In another example, when suitable magnetocaloric compounds supporting continuous magnetic cooling from ~ 300 to ~ 20 K are developed, the energy penalty incurred during hydrogen liquefaction using the conventional gas-compression approach may no longer be a limiting factor preventing the widespread use of liquid hydrogen fuel in transportation. It is conceivable that many other areas where conventional refrigeration is inapplicable because of scaling difficulties and/or where thermoelectric refrigeration demands too much energy, magnetic refrigeration will eventually emerge as the cooling technology of choice.

To amplify the MCE, conventional wisdom calls for increasing the magnetic field change in addition to maximizing both the derivative, $|(\partial M(T, B)/\partial T)_B|$, and the region of magnetic fields and temperatures where the magnetization remains highly sensitive to temperature (see eqns [1]–[5]). Considering the current state-of-the-art of permanent magnet alloys and magnet design, it is quite unlikely that magnetic fields in excess of about 2 T at a reasonable cost will become common in the foreseeable future. That is why maximizing the MCE by manipulating chemical and phase compositions, atomic, microscopic, and magnetic structures of a material appears to be the most realistic option in order to reach the strongest possible MCEs in readily available magnetic fields. Although it remains a formidable challenge for basic science, a better understanding of the MCE, including the ability to control a variety of chemical, structural, and physical degrees of freedom that define the properties of solids will lead to improved existing materials and should eventually result in novel compounds exhibiting large MCE.

An especially promising area of research is the study of the extensive measure of the MCE, that is, the isothermal magnetic-field-induced entropy change that can be strongly enhanced by the added entropy of a structural transition (see eqn [6]). Provided the magnetic field completes the polymorphic transformation, this additional entropy is magnetic field independent, and therefore, may account for more than half of the observed MCE, especially in relatively weak magnetic fields. The design of novel materials exhibiting potent MCEs in weak magnetic fields is, therefore, possible by ensuring that (i) a structural transition can be triggered and completed (or nearly completed) by a weak magnetic field; (ii) the transformation has low thermal and magnetic field hystereses, that is, is reversible, and (iii) the difference between the entropies of different polymorphic modifications is maximized.

Introduction

Manganites were discovered in 1950 (Jonner and van Santen). The materials are named after the manganese ion which is a key ingredient of the compounds due to its mixed-valence state. Unlike the usual ferromagnetics, the transition of manganites to ferromagnetic state is accompanied by a drastic increase in conductivity. Such transition from an insulating to a metallic and magnetic state is a remarkable fundamental feature of these materials. Another fundamental property is the colossal magnetoresistance effect (CMR); one can observe a thousandfold (!) change in the resistance in the presence of a moderate applied magnetic field.

The chemical composition of the manganites is $A_{1-x}R_x\text{MnO}_3$; usually $A \equiv \text{La, Pr, Nd}$ and $R \equiv \text{Sr, Ca, Ba}$. The compound $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ is the most studied material.

Structure

The parent (undoped) compound LaMnO_3 has a perovskite structure which is a distorted cubic lattice. The ideal crystal unit is shown in Figure 1. It is essential that the Mn ions are caged into oxygen octahedron, so that it is surrounded by six oxygen ions (Figure 2). Each oxygen ion is shared by neighboring octahedra. The fivefold orbital degeneracy is split by the crystal field into two well-separated terms, t_{2g} and e_g (Figure 3). The t_{2g} -level contains three electrons forming the so-called “ t -core.” The last d -electron (e_g -electron) is in a loosely bound state. The e_g -electron plays a crucial role in conduction and in other properties of manganites as well as in determining its magnetic order.

Doping: Phase Diagram

The phase diagram of manganites is very rich and contains many different phases. The parent compound, LaMnO_3 , is an insulator and its transition to the conducting state is provided by doping. The doping is realized through a chemical substitution, for example $\text{La}^{3+} \rightarrow \text{Sr}^{2+}$, that is, by placing a divalent ion into the local La^{3+} position. Such substitution leads to the change in the valence of the manganese ion valence: $\text{Mn}^{3+} \rightarrow \text{Mn}^{4+}$. That is why manganites are often called “mixed-valence magnetic oxides.” The four-valent state of the Mn means that the ion loses its e_g -electron. The missing electron can be described as a hole which is spread over the unit cell, being shared by eight Mn ions (see Figure 1).

As a result, one obtains a crystal $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$, where a number of La centers are randomly substituted by the Sr-ions. Even in the presence of some holes, the crystal, at first, continues to behave as an insulator. This is due to the fact that each hole is localized and the localization corresponds to the formation of local polarons. Such insulating state is preserved with an increase in doping up to some critical value $x=x_c \approx 0.16\text{--}0.17$. At $x=x_c$, the material makes a transition into the conducting (metallic) state which persists with further doping up to $x \approx 0.5\text{--}0.6$, depending on the chosen composition.

It is remarkable that the transition at $x=x_c$ is also accompanied by the appearance of the ferromagnetic state. As was noted above, the correlation between conductivity and magnetism is the most fundamental feature of manganites. The conductivity of the best samples of the Sr-doped films at low T is of order $\sigma = 10^4 - 10^5 \Omega^{-1} \text{cm}^{-1}$, and this corresponds to a typical metallic regime.

Continuous increase in doping leads to the transition from the metallic to insulating state. For many compounds one can observe a peculiar charge-ordered state. The right end of the phase diagram (e.g., SrMnO_3) describes the compound which does not have the e_g -electrons. Naturally, this material is an insulator.

If the compound is in the metallic ferromagnetic state (e.g., it corresponds to $0.2 < x < 0.5$ for $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$), and temperature is increased (at fixed x), then at T_C (T_C is the Curie temperature) one can observe transition to the low-conducting paramagnetic state which contains local distortions. The conductivity in this state has a hopping polaronic nature.

Main Interactions: Hamiltonian

The loosely bound e_{2g^-} -electron is the key player in the physics of manganites. Its Hamiltonian can be written in the form:

$$\hat{H} = \hat{H}_t + \hat{H}_H + \hat{H}_{\Gamma} \quad [1]$$

where

$$\hat{H}_t = \sum_{i,\delta} \hat{t}_{i,i+\delta} \quad [2]$$

$$\hat{H}_H = -J_H \sum_i \hat{\sigma} \cdot S_i \quad [3]$$

$$\hat{H}_T = \sum_i g \hat{\tau}_i Q_i \quad [4]$$

Here $\hat{t}$ is the two-by-two hopping matrix, $\hat{\sigma}$ is the Pauli spin matrix, S_i is the spin of the t -core, $\hat{\tau}$ is the pseudospin matrix, and Q_i is the normal mode.

The first term on the right side of eqn [1] describes the hopping of the e_{2g} -electron. The second term is the Hund's interaction which polarized the carrier's spin, and the last term corresponds to the Jahn–Teller effect which reflects the double degeneracy of the e_{2g} -term. The strength of the Hund's interaction is of the order $J_H \approx 1$ eV; this is the largest scale of the energy. It is also essential that, because of the Hund's interaction, the conducting e_{2g} -electrons are spin-polarized. As for the hopping and the Jahn–Teller terms, they are of order $t \approx g \approx 0.1$ eV, so that $t \approx g < J_H$.

The nature of the ferromagnetic spin alignment in manganites is different from that for usual ferromagnets. The concept, so-called “double exchange” mechanism was introduced in 1951 by Zener. Qualitatively, the nature of the mechanism is as follows. If one of the Mn^{3+} ions becomes four-valent (e.g., as a result of the $La^{3+} \rightarrow Sr^{2+}$ substitution, implying $Mn^{3+} \rightarrow Mn^{4+}$), a hole appears on this site. It allows for another e_{2g} -electron localized initially at the neighboring Mn^{3+} ions to jump on the new vacant place (this can be described as the hole moving in the opposite direction). But the e_{2g} -electron is spin-polarized because of the Hund's interaction with its t -core. Relative orientation of spins of the e_{2g} -electron and the “vacant” t -core drastically affects the hopping. For example, if the direction of the spin of the core for the Mn^{4+} ion is opposite to that one for the e_{2g} -electron of the neighboring Mg^{3+} ion, then the hopping is spin forbidden. At the same time, such hopping as any increase in a degree of delocalization is energetically favorable. As a result, the ground state of the ferromagnetically ordered system (all spins are polarized along one direction) energetically is below the state which is not ordered. That is why the t -cores become ferromagnetically ordered, and this, in its turn, favors “jumping” of the e_{2g} -electrons, and, therefore, conductivity. Such mechanism (it is called “double exchange”) leads to ferromagnetism and to a strong correlation between ferromagnetism and conductivity.

Metallic Phase: CMR Phenomenon

Consider the sample in the metallic ferromagnetic state with a fixed carrier concentration, (e.g., $x=0.3$) and then increase the temperature. Such ferromagnetic state persists up to the Curie temperature. For example, for the $La_{0.7}Sr_{0.3}MnO_3$ to the value of $T_C \approx 170$ K. Above this temperature the compound makes the transition into paramagnetic state. In addition, resistivity drastically increases (almost insulating state).

The conductivity of the metallic manganites is provided by the delocalized e_{2g} -electrons. It is essential that these electrons are in the double-degenerate state. This leads to the two-band picture. Presence of the two energy bands allows to explain the absence of the electron–hole symmetry for the phase diagram. In addition, this feature is important for analysis of various properties of manganites. For example, optical properties are, mainly, due to the interband transitions.

The value of the Fermi energy in the metallic manganites is small relative to ordinary metals. Its value depends on the doping level and is of the order of $EF \approx 0.2$ eV. As for conductivity, its value depends strongly on the quality of the samples. As was mentioned above, for the best samples it reaches the value $\sigma \approx 10^5 \Omega^{-1} \text{cm}^{-1}$.

The charge transfer in the conducting ferromagnetic manganites is provided by spin-polarized electrons. Because of such spin specifics a total number of carriers in the band of the metallic manganites is twice less than in usual metals. That is why the conducting state in manganites is called “half-metallic.”

The magnetoresistance is a very important parameter of manganites. It is defined as

$$\Delta R/R_H = [R(T, H) - R(T, 0)]/R(T, H) \quad [5]$$

The magnetoresistance has a sharp peak near the Curie temperature for the manganite, and the change in resistivity caused by an applied magnetic field can be huge. Such phenomenon which is dubbed as the colossal magnetoresistance effect (CMR) has been initially observed in the ferromagnetic metallic films by Jin *et al.* in 1994. It turns out that for $La_{0.67}Ca_{0.33}MnO_3$ films $\Delta R/R_H \approx -1.3 \times 10^3$ (!); $H \approx 5$ T.

The CMR phenomenon is discussed now. Below T_C the sample is characterized by usual metallic conductivity. Contrary to it, above T_C it has a large resistivity (low conducting state with hopping polaronic transport). The presence of an external magnetic field allows to establish ferromagnetic ordering at temperatures higher than T_C ($H=0$). The magnetic order provides metallic conductivity, because of the double exchange mechanism, and this leads to a large shift $\Delta R_H = R(T, H) - R(T, 0)$. The shift is negative, in accordance with the experimental observation and corresponds to the transition from a low conducting (almost insulating) to a metallic state.

Insulating State

The undoped material LaMnO_3 is an insulator and its magnetic ordering corresponds to the so-called A-structure. This structure is characterized by the presence of the ferromagnetically ordered layers with an opposite direction of the magnetization for the neighboring layers. In other words, ferromagnetism in layers is combined with the antiferromagnetic ordering in the direction perpendicular to the layers. The value of the Neel's temperature is relatively low ($\approx 10^2$ K).

The insulating behavior can be explained in the framework of the band picture. However, this picture should be modified in accordance with the Hamiltonian (eqn [1]). Unlike ordinary metals, the band is filled by spin-polarized electrons. Moreover, the degeneracy of the e_{2g} -state leads to the two-band situation. In addition, one should take into account the Jahn–Teller distortion. Because the O ion is shared by neighboring manganese octahedra, the cooperative Jahn–Teller effect is dealt with. If one includes all these factors, the energy bands appear to be filled, and the compound is the band insulator.

Doping leads to creation of holes, but it does not mean that the sample becomes a conductor. Initially holes are localized by Coulomb forces and form polarons. Such process is a favorable one for the layered system, because in the 2D case there is no energy barrier for the polaron formation. The transition to the metallic ferromagnetic state occurs at finite doping level $x=x_c$.

Percolative Transition

The doping leads to the situation when at some critical concentration of the dopant, x_c , one can observe the transition from insulating to metallic state. This transition can be described in terms of the percolation theory. Indeed, doping leads to the formation of the compound $\text{A}_{1-x}\text{B}_x\text{MnO}_3$. A position of atom B, which is a substitution for a parent atom, is completely random, and the statistical distribution of dopants leads to the percolation picture. As a result of initial doping metallic clusters are formed. These clusters are created inside the insulating matrix and eventually form the percolation “path.” In accordance with the Zener's double-exchange mechanism, there is ferromagnetic order inside the clusters. The transition to the metallic ferromagnetic state corresponds to formation of the infinite cluster and, correspondingly, to an appearance of the macroscopic phase. The transition occurs at $x=x_c \approx 0.17$, and this value is, indeed, an invariant of the percolation theory. Therefore, the metal–insulator transition in manganites is a percolation phenomenon (Figure 4).

The percolative nature of the metal–insulator transition implies the inhomogeneity of the system, that is, one is dealing with a coexistence of two phases: metallic and insulating. This is the “phase-separation” phenomenon. This concept for the doped oxides was introduced by Gor'kov and Sokol in 1987. Manganites as well as the high-temperature superconducting cuprates are examples of such systems. Macroscopic properties at $x < x_c$ are determined by the insulating matrix, but the sample contains metallic ferromagnetic inclusions. In a similar way, the sample at $x > x_c$, being in the ferromagnetic metallic phase, contains insulating regions.

Figure 4 Temperature dependence of resistivity (for various levels of doping). The transition to the metallic state occurs at $x \approx 0.17$. (Reproduced with permission from Urishibara A, Moritomo Y, Arima T, Asamitsu A, Kido G, *et al.* (1995) Insulator–metal transition and giant magnetoresistance in $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$. *Physical Review B* 51: 14103.)

The percolative transition occurs also in the metallic sample with a fixed-level doping (e.g., $x \approx 0.3$) at $T = T_C$. The fast increase in conductivity $\sigma(T)$ at $T < T_C$ is described by the expression

$$\sigma(T) \propto (T_C - T)^\gamma \quad [6]$$

where γ is a critical index.

The percolative nature of the transition at $T = T_C$ also implies the intrinsic inhomogeneities of the sample, that is, the phase separation. This means that, even below T_C , the sample, being in the metallic ferromagnetic state, contains inclusions of the low-conducting paramagnetic phase.

The concept of intrinsic inhomogeneity as well as the percolation picture has a strong experimental support. Various experimental techniques, such as scanning tunneling microscopy (STM), neutron scattering, X-rays absorption fine structure spectroscopy, and heat capacity data allow us to prove the picture of phase separation. For example, one can measure electronic contribution ($\propto T$) to heat capacity at $x < x_c$. The inelastic neutron scattering as well as the X-rays spectroscopy display the presence of two different bond lengths corresponding to mixed phases. An intensive study of manganites continues. Search for new materials, synthesis of high-quality samples, and a detailed theoretical and experimental analysis of all regions of the phase diagram will lead to new insights and interesting potential applications.

Abstract

In this article we give a general survey of the main properties of magnetic oxides—mostly the oxides of transition metals, but sometime also containing rare earths ions. This is a very rich class of materials, among which there are insulators and metals, systems with insulator-metal transitions, and there are among them even high-temperature superconductors. One of the main features of these compounds, which attract to them special attention and which serve as a basis of many applications, are their rich magnetic properties. In this article we discuss the main physical effects determining their behavior, and describe in detail especially their magnetic properties, but not only. After shortly discussing the basic structure of isolated magnetic ions, we concentrate on the collective effects depending on the interaction between sites, especially exchange interaction, giving rise to different magnetic properties: different types of magnetic ordering in conventional systems, but also more exotic states such as spin liquid states in frustrated systems. We also cover related phenomena in magnetic oxides, such as magnetoelectric and multiferroic behavior, and discuss at the end their diverse useful properties serving as a basis of many applications.

Key points:

- There are different factors such as the spin-orbit coupling, intra-atomic Hund's exchange, crystal-field splitting and the Jahn-Teller effect controlling electronic and magnetic properties of isolated magnetic atoms.
- Intersite effects e.g., electron tunnelling between ions, strong electronic correlations or features of the Fermi surface (in metals) define exchange interaction between magnetic ions.
- Exchange coupling can be anisotropic (different between different spin components). Competition between different exchange bonds can result in very unusual magnetic structures and can lead to different anomalous magnetic states such as spin liquids and spin ice.
- There are insulating magnetic oxides (magnetoelectrics and multiferroics), in which one can influence magnetic state by electric field and, vice versa, electric polarization can be controlled by magnetic field.
- Various transitions including structural and metal-insulator transitions are possible in magnetic oxides. Moreover, some of them can be driven into a superconducting state.
- Magnetic oxides have many applications, e.g., they can be used as magnetic field sensors, for nondestructive control and in spintronics.

Introduction

Magnetism is a big and important part of fundamental and applied physics. There exist many different magnetic materials. There are among them many metals, alloys and intermetallic compounds, but also many insulators displaying rich and interesting magnetic properties. For many applications insulating magnetic materials are preferred, because they have less losses, can be used in combination with optics, etc.

Among insulating magnetic systems oxides represent probably the largest and most important group with rather diverse properties, and they already have many applications. The origin and magnetic properties are often rather different in metals and in insulators. Basic physics of magnetic oxides is quite rich, see e.g., the phase diagram of manganites shown in Fig. 1, and one can demonstrate on it many fundamental physical phenomena in solid state physics. Discussion of these the main topic of the present chapter.

When speaking of magnetic oxides, one typically has in mind oxides of transition metals (TM), most often of $3d$ elements, but $4d$ and $5d$ and rare earths (RE) compounds become more and more popular and these systems have brought many interesting effects to the field. This chapter will be mainly focused on the most important case of TM oxides, but some comments are made also about RE compounds.

Isolated magnetic ions in a crystal

TM oxides are mostly insulating systems. The crucial role in their properties is played by electrons of partially-filled d -shells (or $4f$ -shells for RE systems). The d -electrons, and even more so f -electrons, have relatively small radius, and they often can be treated as localized at corresponding ions. Such localized electrons have simultaneously also localized magnetic moments, and these are mainly responsible for magnetism of corresponding substances.

Fig. 1 Phase diagram of $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$. AFM-A and AFM-G stand for antiferromagnetic structure of the types A and G, see Fig. 10 (a); FMI stands for ferromagnetic insulator, CO: charge ordering.

The d -electrons have an orbital moment $l = 2$, i.e., for an isolated atom or ion they are $2l + 1 = 5$ -fold degenerate, $l_z = -2, -1, 0, +1, +2$. In crystals such as TM oxides (NiO ; Fe_2O_3 , etc.) TM ions are usually located in ligand “cages” formed by anions, like O^{2-} , F^- etc., e.g., they sit in oxygen octahedra or tetrahedra. In this situation the point symmetry becomes lower: instead of spherical symmetry for isolated ions it becomes cubic or even lower due to the influence of ligands, such as oxygens. In cubic symmetry (regular octahedra or tetrahedra) the fivefold degenerate d -levels are split into a doublet e_g and triplet t_{2g} , doublet lying higher than triplet in octahedra (right part of Fig. 2a); the order of these levels being reversed in tetrahedra, left part of Fig. 2a. There exist also other co-ordinations, e.g., trigonal prisms or trigonal bipyramids, the crystal-field (CF) splitting in these cases is shown in Fig. 2a.

This CF splitting (for TM ions in octahedra or tetrahedra it is usually denoted as $\Delta_{\text{CF}} = 10\text{Dq}$) is caused by two mechanisms: (1) by the Coulomb interaction of respective electron density of corresponding orbitals. The typical shape of the five d -orbitals is shown in Fig. 2b, with the charges of surrounding ligands (here O^{2-} ions), and (2) by the covalency of d -electrons with the $2p$ orbitals of oxygens. Both mechanisms usually lead to qualitatively the same CF splitting, the second mechanism (d - p covalency) typically playing more important role.

These CF levels are filled one by one by respective d -electrons. Then one has to take into account different interactions between d -electrons, the most important being here the Hund's rule interaction which can be written as, e.g., $-J_H S_{i\alpha} S_{i\beta}$ (i is the site index, α and β —orbital indices and $\alpha \neq \beta$, S is spin, J_H is the Hund's intra-atomic exchange parameter), and also the spin-orbit coupling (SOC), which for single electron is $\zeta \vec{l} \vec{s}$, but which for the resulting many-electron terms with the total spin $\vec{S}$ and total orbital moment $\vec{L}$ per site is usually written as $\lambda \vec{L} \vec{S}$, where $\lambda = \zeta/2S$ is the spin-orbit coupling constant (Landau and Lifshitz, 1965). SOC strongly increases in going down in periodic table, $\lambda \sim Z^2$ (Landau and Lifshitz, 1965), where Z is the atomic number of the element. It is relatively weak for $3d$ ions ($\lambda \sim 20 - 70$ meV) (Abragam and Bleaney, 1970), but it becomes much stronger, up to ~ 0.4 eV, for $4d$ and $5d$ ions; it often determines the properties of these compounds.

The usual filling of one-electron levels for weak SOC is determined by the interplay of CF splitting and the Hund's interaction (10Dq vs. J_H). If $J_H > 10\text{Dq}$, which is mostly the case of $3d$ oxides, electrons of TM ions with d^n configuration fill d -levels one by one from below such as to give the maximum total spin (e.g., $S = 5/2$ for d^5 configurations, Fig. 3 left part). This is the so called high-spin (HS) state, typical for $3d$ ions. But if $J_H < 10\text{Dq}$, which is usually the case for $4d$ and $5d$ ions, one would better fill the lowest CF levels, which e.g., for the d^5 configuration would give not $S = 5/2$ as for HS configuration left part of Fig. 3, but $S = 1/2$, right part of Fig. 3 (for other electron configurations the exact criterion could be modified, e.g., 10Dq vs. $2J_H$, or vs. $3J_H$). This is e.g., the situation for Ru^{3+} in RuCl_3 and Ir^{4+} in Na_2IrO_3 —the very interesting materials with the strongly bond-dependent (so called Kitaev) exchange interaction and with nontrivial properties, see Section “Exchange interaction”. This is the low-spin (LS) state, typical for $4d$ and $5d$ oxides, but also met in some $3d$ systems, e.g., those with the d^6 configuration (Fe^{2+} , Co^{3+}) in octahedra, for which six d -electrons may completely fill the lowest t_{2g} levels making the LS state of these ions nonmagnetic, $S = 0$. This is exactly the situation

Fig. 2 (a) Crystal-field splitting of d -orbitals for different types of local surrounding of TM ions. (b) Five d -orbitals, the situation of octahedral surrounding is shown. Ligands are red balls.

Fig. 3 Two different spin states in case of d^5 electronic configuration.

in the famous LaCoO_3 , which is non-magnetic at low temperature, but experiences the spin-state transition to magnetic state under heating (particular scenarios are still debated), due to a thermal expansion resulting in decrease of the CF splitting.

The spin-state transitions (known also as spin crossovers in chemistry) are very important for geoscience, since under the pressure (deep in the Earth) TM-ligand distances are strongly decreased and therefore the CF splitting in contrast is increased, transforming TM ions into the LS state. Such transitions are accompanied by the change of the volume and manifests itself by variation of the density affecting seismic compressional velocities.

In certain situations the electronic filling of CF levels in symmetric situation (e.g., regular octahedra) may be such that there remains an orbital degeneracy, either double (one or three electrons on the e_g levels) or triple (partially-filled t_{2g} levels). In this case, according to the famous Jahn-Teller (JT) theorem, the symmetry of the system would spontaneously lower, leading to splitting of degenerate levels and giving a gain in electronic energy, linear in distortion, overcoming the quadratic loss of elastic energy (Kaplan and Vekhter, 1995). The spin-orbit coupling can affect the Jahn-Teller effect (Streltsov and Khomskii, 2020). The well-known ions with strong Jahn-Teller effect are e.g., Mn^{3+} and Cu^{2+} , important in manganites with colossal magnetoresistance (CMR) and in High-Tc superconductors, see below.

Intersite effects

While the ground state can be defined by the single-site physics, the intersite effects of different types are extremely important—in particular this is the intersite electron hopping. The actual hopping could lead to conductivity, eventually making the system metallic. The virtual hopping due to a quantum tunnelling in insulating situation can give rise to exchange interaction. In this case, when we allow for the change of the number of electrons at a site, the intra-atomic Coulomb interaction between electrons starts to play crucial role. In the simplest form, first ignoring orbital degrees of freedom, one can describe the situation by the Hubbard model

$$H = -\sum_{ij\sigma} t_{ij} c_{i\sigma}^\dagger c_{j\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow} \quad (1)$$

where i, j numerate lattice sites and σ is the spin index. The first term describes the intersite hopping of (here nondegenerate) electrons, and the second term is the on-site Coulomb (Hubbard) interaction. For one electron per site we can have here two situations. If $U \ll t$, the dominant role is played by the first term in (1), intersite hopping, which after Fourier transform gives the partially-filled (here half-filled) energy band and consequently a metallic state with itinerant electrons. Interaction U , assumed here to be weak, can then be treated e.g., by perturbation theory. This is the standard band theory of solids.

In the opposite case of $U \gg t$, however, the situation is very different. To avoid strong Coulomb repulsion the electrons would remain localized one per site. This is the state apparently first suggested by Peierls, the theory of which was later developed largely by Mott; this state is now called Mott insulator (Khomskii, 2014). It is this state which is the basic state of most magnetic oxides: the presence in it of localized electrons also means the presence of localized spins, or localized magnetic moments. Very schematically one can describe the general situation on a simplified diagram showing the evolution of one-electron bands with increasing Coulomb (Hubbard) repulsion U , characterizing on-site electron-electron repulsion. Here the half-filled metallic band existing for $U = 0$ transforms into two bands: the lower and upper Hubbard bands for U more than the critical value U_c (of order of the bandwidth $W = 2zt$, where z is number of nearest neighbours). These bands are divided by the energy gap $\sim U$, so that the lower band is filled and the upper one is empty. (One has only to remember that it is an effective picture, with the gap created by electron-electron repulsion, in which case the simple one-electron description is, strictly speaking, not valid. Specifically, the “volume”, the number of states in each Hubbard band is not a constant but depends on the total number of electrons).

In realistic situations we have to take into account also the factors described in Section “Isolated magnetic ions in a crystal”, mostly connected with orbital degrees of freedom of d -electrons. And of course, a lot depends on the type of respective crystal lattice (rock salt in monoxides like MnO , NiO ; corundum structure M_2O_3 , e.g., Fe_2O_3 , Cr_2O_3 ; perovskites AMO_3 , e.g., LaMnO_3 ; spinels with the general formula AM_2O_4 , etc.) (Imada et al., 1998).

Very important is also to realize that usually there are anions, such as oxygen ions, between TM ions in real TM oxides. Sometimes it is sufficient to describe the situation keeping only d -electrons, as we did above, but often p -electrons of oxygen play also an important and, in some cases, crucial role. For example, in perovskites the oxygen ions are located just in between TM ions, so that the effective electron hopping between TM ions occurs via p -states of intermediate oxygens. One can describe this situation by the effective d - p model, including also p -electrons of oxygen:

$$H_{dp} = \sum_{i\sigma} \varepsilon_d d_{i\sigma}^\dagger d_{i\sigma} + \sum_{ij\sigma} t_{ij}^{pd} d_{i\sigma}^\dagger p_{j\sigma} + \text{h.c.} + U \sum_i n_{i\uparrow}^d n_{i\downarrow}^d \quad (2)$$

where t^{pd} is the hopping between TM d - and ligand p -orbitals ε_d and ε_p are their energies. If necessary, one should include in this description also other interactions: between d - and p -electrons, p - p interaction etc. If the oxygen p -levels are deep below d -levels of TM ions, one can exclude p -electrons and return to the description of the type of Hubbard model $\tilde{t}_{dd} \sim t_{pd}^2 / (\varepsilon_d - \varepsilon_p)$, with the effective hopping $\tilde{t}_{dd}$ (more accurately one has to include here in the denominator also the effects of electron-electron interactions, which, however, may be not so important for large $\varepsilon_d - \varepsilon_p$). However if p -levels lie not far from the d -levels, the situation may change drastically. In this case the ground state may still be the same—electrons localized at TM ions, a magnetic insulator. But the lowest

Fig. 4 Sketch illustrating formation of the lower and upper Hubbard bands due to the on-site electron-electron repulsion (characterized by the Hubbard's term U). The schematic bands and the density of states are shown.

excited states are not those following from the simple Hubbard model (1) and shown in Fig. 4, i.e., not the transfer of a d -electron from one TM ion to the other, the process $d^n d^n \rightarrow d^{n+1} d^{n-1}$, which costs the energy U , but the lowest charge-carrying excitations would be the transfer of a p -electron from the O^{2-} ion to the d -shell of TM, the process $d^n p^6 \rightarrow d^{n+1} p^5$, with the creation of an oxygen hole. The energy cost of this process is called the charge transfer (CT) energy (Sawatzky and Green, 2016)

$$\Delta_{CT} = E(d^{n+1} p^5) - E(d^n p^6) \quad (3)$$

Crudely speaking, this CT energy is, according to (2), $\Delta_{CT} = \varepsilon_d - \varepsilon_p + U$, but it can also depend on the pd and pp -interactions. Correspondingly all correlated insulators can be subdivided into two big groups, see the famous Zaanen-Sawatzky-Allen diagram in Fig. 5. Thus depending on the ration between the Hubbard and CT energies we can have two types of insulators: the usual Mott insulators if $\Delta_{CT} > U$, and CT insulators for small CT energy if $\Delta_{CT} < U$. As always, the insulating states exists if both U and Δ_{CT} are larger than the electron hopping t . In the opposite case we can have metallic state for Mott part of the phase diagram, and rather nontrivial situation—possibly metallic but also sometimes insulating states, if we move on this phase diagram to the left, to the region of small or negative CT energy. We will discuss this situation below in Sections “Insulator-metal transitions; metallic oxides” and “Superconductivity in oxides”.

Exchange interaction

There are various mechanisms which contribute to exchange interaction between magnetic centers in oxides. The simplest Hamiltonian to describe this interaction was proposed by Werner Heisenberg,

$$H = \sum_{i>j} J_{ij} \vec{S}_i \vec{S}_j \quad (4)$$

who suggested that the non-local part of the Coulomb repulsion between electrons at different sites (numerated by indexes i and j) is responsible for this interaction; the strength of which is controlled by exchange constants J_{ij} . However, it was later understood that in most cases the mechanism of exchange interaction in magnetic insulators such as TM oxides is very different. In these systems electrons are mostly localized at their sites, but due to the virtual hopping, described by the first term in (1) they can tunnel between magnetic ions, which leads to decrease of total energy. However, the Fermi statistics and intra-atomic Hund's exchange interaction strongly affect this tunnelling. In elemental example sketched in Fig. 6a the hopping between FM ordered spin is forbidden by the Pauli principle and for this state we do not gain energy; therefore quantum tunnelling will stabilize AFM interaction with $J \sim 4t^2/U$ (Goodenough, 1963). If the hopping occurs directly between d -orbitals one speaks about the direct exchange, but often

Fig. 5 Zaanen-Sawatzky-Allen diagram. It classifies insulators according to the character of the states forming valence and conduction bands. Here U_{dd} is the Hubbard on-site electron repulsion parameter, Δ_{CT} —charge-transfer energy, t_{pd} —tunnelling amplitude (hopping) from p -orbital of a ligand to d -orbital of TM ion.

Fig. 6 (a) Sketch illustrating mechanism of the direct exchange or super exchange (for one active orbital per site): in case of FM order tunnelling processes are forbidden and cannot lower the total energy of the system, but this energy gain exist for antiparallel spins, i.e., this process leads to AFM coupling. (b) Mechanism of the double exchange leading to FM: itinerant electrons easily propagate through the lattice in case of FM order, thus gaining kinetic (band) energy, since they follow the first Hund's rule at every site.

magnetic ions are too far away from each other and d -electrons can hop only via ligand's p states. This is what is called the super exchange interaction. In real materials the situation is much more complicated, there are in fact many orbitals (five in case of TM) and there can be quite a few possible hopping paths resulting in various contributions to the total exchange, see also Section “Frustrated magnetism, spin liquids, spin ice”, but still the strongest exchange (for appropriate filling of orbitals) is AFM as in Fig. 6a. This is why most of insulating TM oxides are AFM, and there are only few FM ones among them, such as, e.g., YTiO₃ or NaCrGe₂O₆, with typically low Curie temperatures (Streltsov and Khomskii, 2017).

Going to metallic magnetic oxides one needs to mention two other important exchange mechanisms. The first one is the so-called double exchange. Suppose there are two groups of electrons—localized and itinerant, as, e.g., in Sr doped LaMnO₃ where t_{2g} electrons are localized at Mn sites, while e_g orbitals are very different—these d -orbitals are directed exactly to each other in perovskite structure of LaMnO₃ and therefore corresponding bands are much wider. Moreover, due to not complete filling these e_g bands are metallic. Thus, there are localized t_{2g} electrons forming localized magnetic moments, and e_g ones moving on the background of these moments as illustrated in Fig. 6b. It is clear that it is much easier for them to propagate if all moments are FM, otherwise at every other Mn site e_g electrons appear in the “anti-Hund” configuration. Thus, there is a FM contribution to the exchange interaction due to the presence of such metallic electrons. Again, in real materials there will be competition between the FM double exchange and (typically) AFM super exchange, and the outcome, i.e., the resulting sign of the interaction, is not obvious. In particular, this can result in canting of the spins or in the formation of helicoidal magnetic structures.

The last exchange mechanism to mention is the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction which is characteristic for metallic systems such as metallic RE compounds. A localized moment is known to generate in metals an oscillating spin polarization of conduction electrons. Another magnetic moment interacts with these electrons and therefore feels the presence of the first moment. The resulting RKKY exchange is slowly decaying with distance and is oscillating in space, so that the sign of the RKKY exchange can be both FM or AFM (Yosida, 2010).

It has to be noted that the Eq. (3) often turns out to be oversimplified, there can appear higher order terms in spin variables, but also J is allowed to be not a scalar, but a tensor $J^{\alpha\beta}$, where $\{\alpha, \beta\} = \{x, y, z\}$. Then the diagonal part equal for all spin components gives isotropic exchange $J = J^{xx} = J^{yy} = J^{zz}$, while off-diagonal ones give anisotropic interactions, for example generate Dzyaloshinskii-Moriya (DM) interaction, which can be rewritten in a compact form as $H_{ij}^{(DM)} = \vec{D}_{ij} \cdot (\vec{S}_i \times \vec{S}_j)$, from which it becomes clear that the DM interaction favors spin canting. This is an extremely important interaction, which is responsible for appearance of various non-collinear magnetic structures, in particular skyrmions, and it can result in formation of spontaneous electric polarization in multiferroics via the so-called inverse DM effect, see Section “Magnetoelectrics and multiferroics”.

The microscopic origin of DM interaction is the SOC mentioned in Section “Isolated magnetic ions in a crystal”, it couples the spin space and the real space and can result in anisotropy of the exchange interaction (Abragam and Bleaney, 1970). This can not only generate off-diagonal, but can also make diagonal components of the exchange tensor very different. There can also exist a single-site anisotropy, which result in a situation, when instead of vectors in (4) one has, e.g., only z components of spins in effective spin Hamiltonian, i.e., $H = \sum_{i>j} J_{ij} S_i^z S_j^z$. This is the famous Ising model. Another more exotic situation is realized in Kitaev materials with a layered honeycomb structure, where due to strong SOC, specific lattice geometry and particular t_{2g}^5 electronic configuration the exchange interaction along some of the TM-TM bonds is large for z components of spins, while along other bonds it is large for x or y components, see Fig. 7a. In fact strong Ising-like anisotropy and bond-depended interaction were found in many oxides, e.g., Na₂IrO₃, Li₂IrO₃ (Takagi et al., 2019). These are typically systems with heavy $4d$ and $5d$ TM ions (since the SOC is large for them), with various orbital fillings and very different lattice geometry, such as e.g., double perovskites shown in Fig. 7b.

Frustrated magnetism, spin liquids, spin ice

The anisotropy of exchange interaction strongly restricts possible types of the ground states, and when it is combined with a lattice, which also poses its own constraints on the magnetic ordering, novel interesting physics may appear. A typical example is a triangle

Fig. 7 Left: the crystal structure of one of the Kitaev material, Na₂IrO₃: Ir is in O₆ octahedra, which share edges shown by different colors. Right: corresponding spin lattice with the bond depended exchange interaction: for green bond the largest coupling is between S^y components, for red—S^x, and for blue—S^z. (b) Fragment of face-centered cubic lattice, which form magnetic metals (circles) in double perovskite structure, e.g., in Ba₂CeIrO₆. In both situations strong frustration is observed.

of AFM coupled spins, described by Ising model, shown in Fig. 8. One readily realizes that it is impossible to satisfy all exchange bonds in this situation. This is what is called frustration: a system does not know how to order the spins. This results to a large degeneracy of the ground state. Already a triangular cluster has sixfold degenerate ground state, but when we have a lattice of triangles this number rapidly increases and gives finite entropy at $T = 0$. This has important implications for thermodynamics. There are many such lattices having a triangular motif: such are kagomé (e.g., SrCr₉Ga₃O₁₉), hyper-kagomé (e.g., Na₄Ir₃O₈), garnets (like Gd₃Ca₅O₁₂) or pyrochlore (Pr₂Ir₂O₇). But frustrations are also possible in other situations, e.g., AFM next-nearest neighbor exchange will frustrate AFM Ising chain, or bond-dependent anisotropic interaction in Kitaev model shown in Fig. 7a leads to the situation when each spin “does not know what to do”—exchange interactions along each bond tend to direct it in its own way (along x , y , or z direction).

Frustration suppresses a long-range magnetic order. One of its hallmarks often used in experimental physics is a large frustration parameter $f = |\theta_{CW}|/T_N$, where θ_{CW} is the Curie-Weiss temperature characterizing an average strength of exchange interaction, and T_N is the Néel temperature (or spin glass transition temperature if a system finally freezes in a disordered state), i.e., the temperature at which a long-range magnetic order sets in. Frustration suppresses such a long-range order, and the parameter f is a measure of this suppression. Typically, if $f \sim 5 - 10$, it might be taken as a signature of one might already expect to have some sort of frustration; stronger frustrations give (much) larger values of this parameter. Thus e.g., in CuAl₂O₄ $f \sim 65$, while in SrCr₉Ga₃O₁₉ it exceeds 150. (Note however that in any low-dimensional system the ordering temperature is strongly (logarithmically) suppressed by a weak interlayer of interchain exchange; this should not be mixed with the effect of frustrations).

Frustration can suppress a long-range magnetic order, while spins are still strongly coupled. By analogy with classical thermodynamics such a state with a long-range quantum mechanical entanglement of spins, but absence of a magnetic order is called a spin liquid (do not mix this state with a conventional paramagnetism, where disorder is induced by the temperature). The spin correlator can have a power-law dependence on distance $\langle \vec{S}_i \vec{S}_j \rangle \sim 1/|\vec{r}_i - \vec{r}_j|$ as in so-called algebraic spin liquids or decay exponentially $\langle \vec{S}_i \vec{S}_j \rangle \sim \exp(-|\vec{r}_i - \vec{r}_j|/\xi)$ as e.g., in the Shastry-Sutherland model (physical realization of which is SrCu₂(BO₃)₂). Both theoretical and experimental studies of spin liquids in different models and compounds is one of the most actively developing directions in the modern condensed matter physics (Savary and Balents, 2017), each year hundreds of materials are claimed to host this mysterious state, but most of them finally reveal some sort of long-range magnetic order or appears to be atomically disordered. One of very promising system for realization of the spin-liquid is the mineral herbertsmithite ZnCu₃(OH)₆Cl₂ with the kagomé lattice of Cu²⁺ ions with $S = 1/2$.

One more very interesting subject to mention in context of frustration is the spin ice systems. These are mainly pyrochlores like Dy₂Ti₂O₇, Tb₂Ti₂O₇, in which magnetic ions (Dy, Tb) form the lattice of corner-sharing tetrahedra (again with triangular motif) and are very strong Ising ions, with easy axes directed for each ion to the center of respective tetrahedron (or away from it) (Gardner et al., 2010). This leads for certain interactions (including dipole-dipole interaction) to very strong frustration and to disordered ground state. This situation reminds the crystal structure of conventional ice, where oxygens form distorted tetrahedra, and hydrogen of H₂O molecules can be attached to one or to the other oxygen, i.e., can move to the center of oxygen tetrahedra or away from it. Spins in spin ice materials are directed in the same way as the electric dipoles formed by H⁺ and O²⁻ ions, see Fig. 9; that is why the very term “spin ice”. Many features of spin ice systems are quite exotic, in particular excitations in these systems have properties of magnetic monopoles.

Fig. 8 Illustration of frustration. If the exchange interaction is described by the Ising model and all spins are coupled antiferromagnetically, then they cannot satisfy all exchange bonds.

Fig. 9 Conventional and spin ices. Arrows show displacement of hydrogens (or electric dipole moments) in real ice and spin directions in spin ice.

Various orderings: Magnetic, charge, orbital, etc.

There can be very different magnetic structures in magnetic oxides. Many perovskites adopt simple two-sublattice structures as shown in Fig. 10a (e.g., LaTiO_3 is AFM of G-type; CaCrO_3 is C-type; LaMnO_3 is A-type), but there are also examples of very complex and seemingly counterintuitive structures, where for example spins on different sites can be nearly orthogonal to each other as in UO_2 (Fig. 10b) or $\text{Bi}_2\text{Fe}_4\text{O}_9$. Often this is the result of competition between different exchange couplings, e.g., nearest and next nearest neighbors, but various anisotropic contributions to the exchange tensor $J^{\alpha\beta}$ can also strongly change the ground state magnetic structure; this factor is especially important for $4d$ and $5d$ oxides.

Spin is just one of the degrees of freedom in magnetic oxides. There are also other, such as orbital and charge degrees of freedom. If metallic ions have different oxidation states, e.g., there can be Mn^{3+} and Mn^{4+} ions in the same material, they can be ordered, in which case we speak of the charge ordering or more generally about formation of the charge density wave. There are many examples of magnetic oxides with charge ordering—e.g., Fe_3O_4 , AlV_2O_4 , $\text{Y}_2\text{Ni}_2\text{O}_6$ —and there can be very different mechanisms lying behind this effect. It can be connected with the nesting of the Fermi surface for initially metallic systems. The mechanisms of such charge ordering may be electron-phonon interaction or Coulomb interaction. There may also exist strong coupling of CO with other degrees of freedom. For example, in manganites such as $\text{PrBaMn}_2\text{O}_6$ and $\text{NaMn}_7\text{O}_{12}$ the AFM ordering, the so-called CE-type ordering (Fig. 10c) coexists (and may be caused by) the checkerboard CO of Mn^{3+} (grey circles in Fig. 10c) and Mn^{4+} . The additional electron in e_g shell of Mn^{3+} ions provide strong FM coupling with two of its neighbors by the double exchange mechanism, with this electron occupying $3x^2 - r^2$ or $3y^2 - r^2$ orbitals for horizontal or vertical legs of the zigzag. These three ferromagnetically coupled spins are the example of trimer clusters (“trimerons”) also invoked to explain the details of charge ordering in magnetite Fe_3O_4 .

There exist yet another very important type of ordering in oxides—orbital ordering. It usually occurs in systems with orbital degeneracy and with strong JT effect, see Section “Isolated magnetic ions in a crystal”. Local distortions due to the JT effect on different centers couple to each other, leading to the cooperative effect—cooperative JT ordering, or orbital ordering. This usually occurs at a special transition, which is simultaneously a structural transition with the reduction of the symmetry of a crystal. Besides its own features such orbital ordering also very strongly influences magnetic ordering. As was explained in Section “Exchange interaction”, exchange interaction between the same half-filled orbitals (ferro-orbital situation) results in AFM, see Fig. 6a, while it can be shown that if electrons occupy different orbitals (antiferro-orbital) and there is no overlap between these half-filled orbitals, then the exchange interaction can be ferromagnetic. One of the examples is LaMnO_3 with four $3d$ electrons, one at e_g and three at t_{2g} orbitals. Antiferro-orbital ordering of one of e_g orbital results in FM in the ab plane, while t_{2g} states give AFM along the c direction, see Fig. 11.

There are many examples of magnetic oxides with orbital ordering in addition to mentioned above manganate, but the most important is that in this class of materials—magnetic oxides—spin, orbital, charge and lattice degrees of freedom are often turn out to be interrelated and may affect each other. This feature is interesting from theoretical point of view and opens up new perspectives for technological application of such systems, for example one can change electronic properties by stress or magnetic properties by external electric field or light.

Fig. 10 (a) typical types of AFM structures for a simple cubic lattice, (b) very complicated AFM structure of UO_2 , (c) CE-type of AFM with FM zigzags, realized e.g., in half-doped manganites like $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$, cf. Fig. 1.

Fig. 11 Orbital ordering in LaMnO_3 (Mn^{3+} , $t_{2g}^3 e_g^1$). Single e_g electron occupies alternating $3x^2-r^2$ and $3y^2-r^2$ orbitals (dubbed as x^2 and y^2), which is the antiferro-orbital (AFO) ordering; it gives ferromagnetism in the ab -plane, see (a). Magnetic coupling along c is predominantly governed by the t_{2g} orbitals. There is a strong overlap between the same t_{2g} orbitals (via ligand's p -orbitals), which results in antiferromagnetism in the c -direction.

Magnetoelectrics and multiferroics

In this article we mainly concentrate on magnetic properties of oxides. However, in several specific situations there appears quite nontrivial electric behavior of these systems, closely connected with their magnetism, so that one can in principle influence magnetic state of the system by electric field. Such are the systems with (linear) magnetoelectric effect (ME), first proposed by Dzyaloshinskii in 1959 on symmetry grounds, the microscopic theory of which later on being elaborated by Moriya. This ME effect is based on the existence in systems with some special symmetries of the term in free energy of the type $\alpha_{ij} E_i H_j$ or $\tilde{\alpha}_{ij} P_i M_j$, where P is an electric polarization and M —magnetic moment, E is electric and H —magnetic field (we assume summing over repeated indices $\{i, j\} = \{x, y, z\}$). The presence of this term in the free energy leads to the possibility to induce magnetization

$$M_i = \alpha_{ij} E_j$$

by electric field or, vice versa, of electric polarization by magnetic field,

$$P_i = \alpha_{ij} H_j$$

The magnetoelectric tensor α_{ij} can have both symmetric and antisymmetric components; the symmetric one leads e.g., to the magnetic moment parallel to the applied electric field, and antisymmetric ME tensor—to the moment M perpendicular to E .

Already a year after this prediction by Dzyaloshinskii the ME effect was found by Atsrov in Cr_2O_3 , and later on it was actively studied in many materials, mostly in antiferromagnetic TM oxides. But the coupling of electric and magnetic properties is not restricted to the ME systems, in which one needs external fields to observe this effect. It turned out that there also exist systems in which magnetic and electric orderings, in particular ferroelectricity (FE), coexist without external fields. Such materials were called multiferroics (MF) (besides magnetism and ferroelectricity one sometimes also includes into this class ferroelasticity, but most often nowadays by MF one means coexistence of magnetism and ferroelectricity). The study of MF materials and of related phenomena was initially started in the former Soviet Union, mainly by the groups of Smolenskii in Leningrad and by Venetsev in Moscow, and by Schmidt in Switzerland, who coined the very term “multiferroic”. After relatively slow start, this field got strong boost at the beginning of 2000-th, starting from works of Ramesh, Kimura and Cheong, and it is now a very well-developed field, with many interesting results and with the promise of important applications (Cheong and Mostovoy, 2007).

As to the physics of MF, there is now pretty good (although of course not complete) understanding of the microscopic mechanisms of MF. All MF can be divided into two big groups. In type-I MF magnetism and ferroelectricity appear independent of one another—although of course connected when both are present!—and are due to different physical mechanisms. Thus e.g., in one of the best MF, BiFeO_3 with perovskite structure, ferroelectricity appears first, at $\sim 1100\text{K}$, and is predominantly due to the lone pairs of Bi^{3+} . At lower temperatures, below $T_N = 643\text{K}$, it becomes AFM due to the ordering of spins of Fe^{3+} . Similarly, in RMnO_3 (R —rare earths like Y , Ho etc.) ferroelectricity and magnetism occur at different temperatures, FE at about 900K , and AFM—at about $T_N \sim 100\text{K}$. Here FE is connected with the rotation and tilting of MnO_5 trigonal bipyramids, and magnetic ordering—with the usual exchange interaction of Mn ions.

Type-II multiferroics, however, are the systems in which the origin of ferroelectricity and magnetism are intrinsically connected and FE appears only in some specific magnetic structures, always in magnetically-ordered state. There are three main microscopic mechanisms of MF behavior in such systems. One is the magnetostriction: in some types of magnetically-ordered states due to magnetostriction there may appear electric polarization, see e.g., Fig. 12. Such are for example TbMn_2O_5 or in $\text{Ca}_2\text{CoMnO}_6$. The second, most widespread and probably the most interesting mechanism of MF in type-II multiferroics is realized e.g., in systems with cycloidal magnetism structures. It was shown in 2005 by Katsura, Nagaosa and Balatsky, and by Mostovoy, that for neighboring canted spins $\vec{S}_i, \vec{S}_j$ there would appear electric dipole moment, or electric polarization

$$\vec{P} \sim \vec{r}_{ij} \times [\vec{S}_i \times \vec{S}_j], \quad (5)$$

Fig. 12 The appearance of electric polarization due to magnetostriction in a system with two types of ions and with magnetic structure up-up-down-down.

Fig. 13 Magnetic cycloid running along x, with spins rotating in the zx plane. According to (5) this results in formation of electric polarization pointing in the z direction.

where $\vec{r}_{ij}$ is the vector connecting these two sites. For cycloidal magnetic structures such dipole moments at every bond add, leading to the net polarization, i.e., to MF behaviours, see Fig. 13.

This is e.g., the mechanism of MF in TbMnO_3 —one of the first such systems discovered. Nowadays there are many other systems, mainly TM oxides, with this property. Microscopically the mechanism of electric polarization in these systems is the inverse DM effect, requiring the presence of relativistic SOC.

There exist also one more, the third microscopic mechanism of MF, also requiring the action of SOC—the SOC-driven modification of d - p hybridization. This mechanism can give MF behavior for example in the helicoidal (proper screw) magnetic structures. But this situation is less common and usually less important in the field of MF.

The study of MF, besides its scientific interest, is largely driven by the possible important applications. The most important of these is the potential possibility to control magnetic memory electrically, without using electric current as in most present magnetic memory devices, but writing and reading magnetic memory just by electric field, like e.g., in gate devices, this avoiding the losses always present when one has electric currents. And one can also make very sensitive magnetic field sensors using MF, with the sensitivity approaching that of SQUID but operating at room temperatures. All in all, this field of research is very active nowadays.

Insulator-metal transitions; metallic oxides

As discussed in Section “Intersite effects”, systems with integer number (e.g., one) of electrons per site and with strong correlations, with the Hubbard’s on-site interaction U larger than the effective electron hopping t or the respective bandwidths $W = 2zt$, are Mott insulators. When one of these conditions is violated, we can have a transition to a metallic state. One can speak of essentially three specific mechanisms of such insulator-metal transitions (IMT). The first one can be called, following Japanese literature, the bandwidths-controlled IMT (Imada et al., 1998). If, keeping the number of electrons the same, one increases the electron hopping t (or decreases the Hubbard interaction U), one can reach the situation when the bandwidths become larger than the electron repulsion, cf. Fig. 4. In this case the system may become metallic, i.e., there will occur in it an insulator-metal (or Mott) transition. This can be reached e.g., by increasing pressure, at which the atoms come closer together and the overlap or electronic functions on neighboring sites, and corresponding electron hopping, increase.¹

Such transitions can be also driven by temperature. These are the most interesting situations. A good example is presented by the vanadium oxides, see Fig. 14. As we see, many of those have a transition from a metallic to an insulating state with change of temperature. Very often such IMT are accompanied by the change of crystal structure, and sometimes—with magnetic ordering. However, they may occur also without change of lattice symmetry. This is seen e.g., in phase diagram of V_2O_3 as a function of pressure (or chemical pressure imitating compressed samples) and temperature, Fig. 15: the transition line at higher temperatures divides paramagnetic metallic from paramagnetic insulating state, with the same corundum structure (but with the jump in volume at this I-order transition). One sees here also the effect discussed above: V_2O_3 becomes metallic at high pressures even at low temperatures. There are many examples of such Mott transitions in different TM oxides.

One can also single out the “subtype” of the same mechanism: IMT transition caused not by increase of electron hopping or a bandwidth, but by the reduction of effective Hubbard repulsion U . It seems at first glance that it is very difficult to modify it—it is a local property of an ion. But it can change for example if in a many-electron atom or an ion the intra-ionic configuration change, e.g.,

¹This general tendency can be violated in certain specific cases, in particular when in an insulating state TM ions form tightly-bound small clusters, e.g. dimers. Formation of such dimers is usually accompanied by the reduction of the volume of the system, and such small-volume insulating state can be stabilized by pressure. But it is a rather rare exception; as a rule one should expect that with increasing pressure Mott insulators could be transformed into metals

Fig. 14 Metal-insulator transitions in various V oxides as seen from temperature dependence of electrical resistance. Adapted from Pergament AL et al. (2013) *ISRN Condensed Matter Physics* 2013: 960627.

Fig. 15 Schematic phase diagram of V_2O_3 in pressure (P) and temperature (T) coordinates.

under pressure. Thus, for example in oxides containing the ion Fe^{3+} (configuration d^5 , with the spin in the HS state $S = 5/2$) such ions transform under pressure to a LS state with the total spin $S = 1/2$ (LS state ions have smaller size than the HS ones). One can show that at this transition the effective value of the on-site Coulomb repulsion strongly decreases (U_{eff} contains not only the direct density-density repulsion, but it also depends on the intra-atomic Hund's rule exchange J_H , and its contribution strongly changes in going from the HS to LS state). One can call this mechanism the interaction-controlled IMT.

The second situation one meets when one changes the electron concentration, e.g., by doping. By that the system can also become metallic. This is the band-filling-controlled IMT. Important to realize is that the metallic state which can thus be created, still may have narrow bandwidths and strongly-interacting electrons. Therefore, such metallic state can have very different properties from those of the conventional metals like Na or Al. They may strongly deviate from the usual free-electron-like or even from Fermi-liquid behavior: the temperature dependence of many properties such as resistivity or Hall effect may be different from those of conventional metals; they may display nontrivial magnetic properties partially resembling those of localized electrons, e.g., may develop different types of magnetic ordering (FM, helicoidal, etc.); they may have different other types of orderings, including charge ordering, discussed above in Section "Various orderings: Magnetic, charge, orbital etc.". A good illustration may be provided by the rich phase diagram of colossal-magnetoresistance manganites like $La_{1-x}Ca_xMnO_3$, shown in Fig. 1. Most interesting, in some such systems one can even have a high-temperature superconductivity, discussed in more details in the next section.

Yet one more special type of IMT and the corresponding class of metallic oxides can appear in systems in which there exist strong interplay of d -electrons of transition metals and p -electrons of ligands, e.g., oxygens. As discussed in Section "Intersite effects", one has in general to include oxygen p -electrons in the discussion, and this can become essential if oxygen p -levels lie close to d -levels of TM. One can characterize it by the CT energy, needed to transfer an electron from O^{2-} ion to d -levels of TM. As mentioned in Section "Intersite effects", if Δ_{CT} is very large one can exclude p -electrons and go to the effective description including only d -electrons, with some effective parameters. But in some cases, especially in systems with high valence of TM, Δ_{CT} can be small

or even negative. In such situation it may be energetically favorable to transfer some p -electrons from oxygens into d -shells of TM, thus creating oxygen holes L —oxygen ions with p^5 configuration. Oxygen hole thus created can start to move in a crystal, creating metallic state. One can call this situation self-doping: one changes concentration of d -electrons and p -electrons not by external doping as in band-filling-controlled IMT, but such process occurs spontaneously due to redistribution of electrons between p -shells of oxygens and d -shells of TM. The properties of such states can be very unusual. Such states can be very important in many materials, in particular in the cuprate High-Tc superconductors discussed in the next section.

Superconductivity in oxides

Usually when speaking on superconductors one has in mind good metals like Pb or Al. Superconducting pairing in those is ascribed to electron-phonon interaction. Magnetism was always considered as the greatest enemy of superconductivity. And in most cases it is indeed true. All the more surprising was the discovery of High-Tc superconductivity by Bednorz and Mueller in 1987 in completely different class of materials: in cuprates, TM oxides usually considered good for magnetism but not for superconductivity. This discovery caused enormous activity continuing to this day and attracted common attention to the physics of correlated electron systems, to TM oxides in general and to cuprates in particular (Keimer et al., 2015).

Cuprate High-Tc superconductors, such as $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ (LSCO) or $\text{YBa}_2\text{Cu}_3\text{O}_7$ (YBCO) contain as the main building blocks CuO_2 planes shown in Fig. 16, i.e., they can be considered as “2D perovskites”.

Formally the valence of Cu in them is Cu^{2+} in undoped LSCO or in oxygen-depleted YBCO, which are actually Mott (or rather charge-transfer) insulators with magnetic ordering. Cu^{2+} is a very strong JT ion, and in these systems it is typically located either in very strongly elongated octahedra, or is fivefold or even fourfold coordinated, i.e., located in square pyramids or just in oxygen squares. The hole in d^9 configuration of Cu^{2+} is sitting on the upper x^2-y^2 orbital, rather well separated from the rest of d -states, cf. the right part of Fig. 2a. Superconductivity appears in these systems when they are hole-doped, so that the formal valence of Cu becomes e.g., Cu^{2+x} in $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$. But “ Cu^{3+} ” thus created is known to be a negative charge-transfer ions, see Section “Insulator-metal transitions; metallic oxides” above, i.e., the large fraction of thus created holes are actually in oxygens. The resulting state can be represented as $\text{Cu}^{2+}L$, with the spins of Cu^{2+} and of the, predominantly oxygen, holes forming singlet states—the Zhang-Rice singlets. In effect one can often reduce the description of cuprates to the one-band Hubbard model, with undoped magnetic systems corresponding to the half-filled case thereof, the holes introduced by doping—Zhang-Rice singlets—playing the role of holes in such nondegenerate Hubbard model.

But in fact, besides the magnetic and superconducting states, one has found in high-Tc cuprates much more complicated behavior—the phases of “strange metals” with non-Fermi-liquid behavior, the phase with a pseudogap, with different presumed types of ordering—see the schematic phase diagram in Fig. 17.

Fig. 16 Basic structure of CuO_2 layer constituting the main building block of High-Tc cuprate superconductors. Blue balls are oxygen ions (one or two apical oxygens can be missing in some members of this family).

Fig. 17 Phase diagram of superconducting cuprates; superconducting region is shown in blue. SC stands for superconducting, AFM: antiferromagnetic phases.

Despite enormous progress in this field, some basic questions, such as the very mechanism of High-Tc superconductivity, and many properties of the normal state for these compositions, still remains open. It is established that in contrast to the usual superconductors the superconducting pairing in cuprates, described by the pairing wave function or the order parameter $\Delta(\vec{k})$, is singlet but not of the *s*-wave type as in most usual superconductors, but is of the *d*-wave type, $\Delta(\vec{k}) \sim |\Delta|(\cos k_x - \cos k_y)$, i.e., it has nodes in certain directions in *k*-space. As to the mechanism of High-Tc superconductivity, it is accepted that it is predominantly not due to the usual electron-phonon interaction, but is largely due to interelectronic interactions. The proximity of High-Tc region to magnetic states is apparently not accidental, magnetic effects seems to play crucial role in establishing superconducting pairing. But the details of this process are still a matter of hot debates, 30 years after the discovery of this phenomenon.

Besides cuprates, yet one more class of high-Tc superconductors was discovered later on, also containing strongly corrected electrons—the iron-based superconductors like LaOFeAs or β -FeSe. Apparently, many properties of these have much in common with those of cuprates, although there are also important differences. As these materials do not belong to oxides, we will not discuss them further.

Various useful properties and applications of magnetic oxides

When speaking of applications of TM oxides, one can point out several specific directions. The first one is the use of their magnetic properties per se. It was in fact the first known in history application—the use in ancient China of magnetite Fe_3O_4 , which is already magnetic at room temperature, for orientation of buildings under construction and for navigation: the first ever compass, on the basis of magnetite, was invented in China about 2000 years ago. Magnetic properties of oxides were used recently in such applications as magnetic memory in computers: the early memory on ferrite coils, more recently using Fe_2O_3 in older hard discs.

More elaborate applications rely on the dependence of various properties of TM oxides such as e.g., electrical resistivity on magnetic order. Thus there are attempts to use colossal magnetoresistance in manganites and some other materials as sensors. Recently there was a big activity in studying topological effects in particular in systems with strongly correlated electrons, among them in oxides. Thus for example topological Hall effect was observed in SrRuO_3 films.

There are the attempts to use magnetic oxides for elaborate thermopower applications. The idea is to use the extra entropy often present in these systems—magnetic, orbital entropy—for entropy transfer, which could make these systems promising candidates for new class of thermoelectric materials.

Strong magnetoelastic coupling and magnetostriction, typical for TM system with unquenched orbital moments, e.g., containing such ions as Fe^{2+} , Co^{2+} , can be used for non-destructive control of metallic products such as gas and oil pipes, etc.

For practical purposes, especially in electronics, the use of thin films is of paramount importance. Investigation of films and multilayers of different materials is going on very rapidly at the moment. TM oxides present an important playground in this direction. Three main factors can lead to the modification of the behavior of films as compared to the bulk. The first one, common for all films independent on their particular type, is spatial quantization, caused by the finite thickness of films restricting motion of electrons, magnons etc. in perpendiculars direction. Two other factors are more specific for TM oxides. First, due to strain imposed by the substrate, both magnetic and especially orbital structure of the material can change. For example, orbital occupation at the first few layers might be very different from that in the bulk. This in its turn can lead to change of exchange interaction and to different type of magnetic ordering in thin films as compared to the bulk. The third factor, important for TM films and multilayers, is the possible charge redistribution connected with the possibility to change the valence of TM ions. Thus, for example when one makes contact of LaMnO_3 with LaNiO_3 , with the valence in the bulk being 3+ for both TM ions, on the interface it is favorable to transfer electrons from Mn to Ni, forming on the contact Mn^{4+} and Ni^{2+} . Indeed, the trivalent Ni is an ion with very small or even negative charge transfer gap and is not very stable: energetically Ni^{2+} is much more favorable. On the other hand, to transform Mn^{3+} to Mn^{4+} does not cost much energy. In effect this charge and valence redistribution on the contact indeed takes place in this situation, and similar phenomena should be considered also for some other combination of TM oxides in a contact.

Some TM oxides can serve as very useful substrates. The most important is SrTiO_3 , but also many other TM oxides are used for this purpose. One can also use by that their transport and magnetic properties. Thus, SrRuO_3 can serve as a ferromagnetic metallic substrate, which is necessary for some applications. All in all, the behavior of TM oxides in thin films and multilayers may be quite diverse, such systems display very rich and interesting properties and can promise important applications.

One more big field in which magnetic oxides are also used widely, is spintronics—the field based on the idea to use not charge but spin of an electron for many applications, e.g., for memory and for logical elements in quantum computers, for controlling transport properties etc. This big and very active field is discussed in other articles in this volume, thus we will not dwell on this anymore; suffice is to say that it is just the diversity of the properties of TM oxides which makes them very useful in different ways in spintronics devices.

And one more important point: one should not forget that the TM oxides are quite widespread in nature and play an important role in many natural phenomena. Oxygen gives almost 50% of the total mass of Earth's crust, ocean water and atmosphere. Also, iron is quite abundant (~5%). And this iron mostly exists in Earth's crust in form of oxides which are essentially magnetic: magnetite Fe_3O_4 —ferrimagnetic, hematite Fe_2O_3 (the main component of ordinary rust)—AFM with eventual spin canting.

Similarly, other TM and RE metal oxides are well represented in the Earth's crust. They are often the main ores used for metal production, especially for iron.

Most of TM oxides in the Earth's crust have some magnetic properties, although for the laymen they are not "magnetic"—they do not attract small metallic objects such as needles or nails: most of these are AFM of some kind. But their magnetic properties are widely used in geophysics for the search of novel useful mineral deposits; magnetometry is one of the most powerful tools in modern archeology, etc. And minerals are inexhaustible source of novel magnetic materials with often exotic properties. Thus, most of novel kagomé systems originate from minerals, which one sees from their names: herbertsmithite, volborthite, kapellasite, atacamite, to name just a few.

Even when a mineral itself is nonmagnetic, adding TM impurities may drastically modify its properties. Thus, the color of many precious and semi-precious stones like ruby or amethyst are due to TM impurities. And such impurities are the main ingredients in modern laser materials, starting from the ruby lasers.

And the last point: magnetic oxides are quite important for many living creatures, they were already in use by them for ages. Long before the compass with the use of magnetite was invented in ancient China, the same principle and the same material was used by birds for the orientation, and there are many other similar examples. Even bacteria may be sensitive to magnetic field, e.g., magnetotactic bacteria, mostly containing microcrystals of the same magnetite Fe_3O_4 . Thus, summarizing this article, we may conclude that magnetic oxides are extremely versatile, interesting and important materials, as for their very rich and diverse properties, for their already existing and future applications, but also for many natural phenomena.

Conclusion

Thus, summarizing this article, we may conclude that magnetic oxides are extremely versatile, interesting and important materials, as for their very rich and diverse properties, for their already existing and future applications, but also for many natural phenomena. In this chapter we describe the main physical phenomena in transition metal oxides determining their properties—mostly magnetic, but also other interesting phenomena, such as insulator-metal transitions, magnetoelectricity and multiferroicity, and even High- T_c superconductivity in some of them. Basic theoretical concepts are shortly described in this chapter, and diverse properties of magnetic oxides are illustrated on many examples. We conclude by shortly mentioning several applications of magnetic oxides.

Abstract

Magnetic nanostructures represent a reach playground for fundamental research in magnetism but also are applied in different areas including but not limited to magnetic data storage, permanent magnets, medicine, printing technologies and deep brain stimulation. This broad range of applications is enabled by the tunability of the composition of magnetic nanoscaled objects, which can consist of magnetic and non-magnetic heterostructures, possess different types of magnetic ordering and be of different geometrical shape. In this chapter, we review fundamentals of magnetic phenomena in magnetic nanostructures, address fabrication and characterization approaches as well as discuss on application scenarios. Considering the recent activities, we introduce also curvilinear nanostructures, strain coupled artificial multiferroics as well as magnetic 2D materials and heterostructures of magnetic materials and topological insulators.

Key points

- Fundamentals of magnetic nanostructures.
- Fabrication and characterization of magnetic nanostructures.
- Applications of magnetic nanostructures.
- Introduce micromagnetic description of nanoscaled magnetic materials.
- Describe magnetization reversal, superparamagnetic transition and finite size effects in low-dimensional magnetic nanoobjects.
- Introduce framework of curvilinear magnetism.
- Describe magnetic textures in magnetic nanostructures including domain walls, vortices and skyrmions.
- Introduce determination of micromagnetic parameters based on experimental data.
- Characterization of magnetic nanostructures including 3D imaging of magnetic textures.
- Introduce application scenarios of magnetic nanostructures.

Introduction

In this chapter we discuss physics and applications of magnetic nanostructures. There are numerous definitions of the term “nanostructure”, although most of them agree on when referring to an object for which there is at least one characteristic dimension in the nanometer scale. According to this definition, as nanostructures one considers not only nanoparticles (three dimensional (3D) objects of nanoscale size in all three dimensions) but also platelet-like objects (3D confined objects yet with only one nanoscale geometrical parameter, namely thickness of the platelet) as well as extended thin films (only thickness of the film is in the nanometer scale). In the following, we will follow this broader definition of the term “nanostructure” still with a bias toward 3D confined nanoobjects. In this respect, in addition to platelets and films, we will focus on regular nanoscale-sized particles. This particle can be either filled inside with the same or different magnetic materials or be nonmagnetic in its interior. In the latter case the object is either a hollow particle like a magnetic shell or a core-shell particle with a core composed of a material possessing no long range magnetic order. The differences of magnetic responses between macroscopic and nanoscale materials are usually attributed to the broken translation symmetry at the surface and enhanced surface-to-volume ratio leading to the appearance of magnetic anisotropies and frustration phenomena. For magnetic materials, a typical size of the object should be compared with the characteristic length which is linked to the exchange length or the width of the magnetic domain wall. For typical 3d ferromagnets like Ni, Fe, Co and their alloys, the characteristic magnetic length is about 5 nm while the domain wall can be in the range from 10 nm (for hard magnetic materials) to 100 nm (for soft magnetic materials). Therefore, magnetic nanostructures can be in either single domain or multidomain states. In this chapter, we will introduce relevant energy terms to describe magnetic interactions on the atomistic level and present their micromagnetic counterpart. As numerous applications of magnetic nanostructures rely on magnetic materials with different type of ordering, our discussion is not limited to ferromagnets but also addresses ferri- and antiferromagnetic materials. Furthermore, novel means of controlling magnetic responses explore electric field control of the magnetic order parameter (magnetization in the case of ferro- and ferrimagnets and vector of antiferromagnetism in antiferromagnets) due to promises of low-energy prospective spintronic and spin-orbitronic devices. The relevant materials (single phase like BiFeO₃ or heterostructures say of ferrimagnetic CoFe₂O₄ core and ferroelectric BaTiO₃ shell) can be characterized by two spontaneous order parameters, namely magnetization and electric polarization. Those materials are named multiferroics and they will be also discussed in the chapter. Another appealing material science platform for nanoscale magnetism is related to the use of magnetic 2D materials like CrI₃ or Fe₃GeTe₂. We will discuss magnetic phase transitions in magnetic 2D materials and spintronic devices, which were recently reported. Furthermore, nanoscale dimensions are relevant for magnetic topological insulators (TIs) especially for heterostructures of TIs with magnetic materials, where physics is determined by the magnetic proximity with a spatial extension in several Å only. These materials and relevant nanoscale devices for energy efficient spintronics will be briefly mentioned as well.

Overview**Magnetic ordering and theoretical description**

In this section, we introduce models to describe magnetically ordered media on atomistic level (Section “Atomistic models”). Then we proceed with the phenomenological description of ordered media on macroscopic level (Section “Phenomenological description”) followed by the discussion of local (Section “Local magnetic interactions”) and non-local (Section “Non-local magnetic interactions”) contributions to the magnetic energy. Furthermore, we discuss equations, which determine equilibrium and dynamic magnetic states (Section “Micromagnetic equations of state”).

Atomistic models

Whether the given substance has a magnetically ordered state is determined by its temperature, crystallographic structure and an ability of its atoms to carry a magnetic moment. At the atomic level, ordering is developed due to the exchange interaction. In a particular case of spatially localized interacting spins of $s = 1/2$ length, the Hamiltonian can be written in the form, suggested by Heisenberg,

$$\mathcal{H}_x = -J \sum_{i,j} \hat{s}_i \cdot \hat{s}_j \quad (1)$$

where J is the exchange integral, $\hat{s}_i$ is the spin operators at i -th site and sum is taken over pairs of neighboring spins. The model of a strong spatial localization of spins assumes the integer number of electrons per ion and discrete energy levels. It works well for materials where magnetic properties are due to $4f$ electrons (rare-earth elements). Furthermore, this model is successfully applied for some materials where magnetic properties are determined by $3d$ electrons. A proper description of $3d$ materials requires taking into account delocalized electrons contributing to the formation of spin polarized energy bands. However, the Hamiltonian (1) often can address the key macroscopic properties of metallic magnets and together with its generalizations be used beyond the $s = 1/2$ assumption. Depending on the sign of J , the exchange coupling is called ferro- or antiferromagnetic. The origin of $J \neq 0$ includes direct (overlapping of wave functions of the nearest magnetic ions) and indirect (e.g., via additional ion of oxygen) exchange mechanisms. In rare-earth elements, the exchange coupling between highly-localized $4f$ electrons is mediated by conduction electrons via the Ruderman-Kittel-Kasuya-Yosida (RKKY) mechanism. We note that RKKY coupling is important to explain the microscopic origin of the antiferromagnetic coupling in magnetic field sensors relying on giant magnetoresistive (GMR) effect (Bruno and Chappert, 1992). Furthermore, interfaces in magnetic multilayer stacks provide additional contributions to the spin coupling resulting in, e.g. chiral interactions as for the case of asymmetrically sandwiched ultrathin ferromagnetic layers like Ta/Co/Pt stacks revealing interfacial Dzyaloshinskii-Moriya interaction (see Section “Local magnetic interactions”) (Wiesendanger, 2016; Fert et al., 2017) and surface anisotropy, which can stabilize out-of-plane easy-axis of magnetization in Co/Pd and Co/Pt stacks (Carcia et al., 1985; Carcia, 1988) as well as giant perpendicular magnetic anisotropy in Ir/Co/Pt multilayers (Lau et al., 2019). Furthermore, the exchange bias effect is characteristic for ferromagnet-antiferromagnet interfaces, which phenomenologically acts as the unidirectional anisotropy and leads to the shift of the magnetic hysteresis loop (see Section “Core-shell particles and exchange bias effect”).

In specific substances, the Hamiltonian (1) should be extended by the squares of nearest-neighbors dot products and/or next-neighbor dot products of spins. If all exchange bonds cannot be in the lowest-energy state simultaneously, the magnet is called to be frustrated. According to the criterion of Toulouse (1977), the plaquette of spins is frustrated if

$$F = \prod_{\langle i, j \rangle} J_{ij} < 0 \quad (2)$$

where the product is performed over all active exchange bonds with integrals $J_{ij} \neq 0$ between i -th and j -th spins in the plaquette. A representative example of the frustrated system is a triangular lattice with the antiferromagnetic nearest-neighbor exchange and spins lying in the lattice plane.

The Hamiltonian (1) allows for a simultaneous rotation of spins on arbitrary angle. Their direction with respect to the crystal lattice is determined by weaker interactions of relativistic nature, such as spin-orbit and dipolar interactions. The simplest case of the influence of the crystal field on a single spin $\hat{s}$ is described by the Hamiltonian of the uniaxial symmetry $\mathcal{H}_{ua} = Ds_z^2$ with D determining zero-field splitting of energy levels. The presence of an external magnetic field H makes relevant the Zeeman term $\mathcal{H}_Z = \mu_B g_{ij} s_i H_j$ with the Einstein summation rule being used, μ_B being Bohr magneton and g_{ij} being anisotropic $\hat{g}$ -tensor. Here, and below Latin subindices for the Einstein summation rule run over x , y and z unless stated otherwise.

The interaction of magnetic dipoles represented by spins is described by the Hamiltonian

$$\mathcal{H}_{\text{dip}} = 2\mu_B^2 \sum_{i \neq j} \left[\frac{\hat{s}_i \cdot \hat{s}_j}{r_{ij}^3} - 3 \frac{(\hat{s}_i \cdot \mathbf{r}_{ij})(\hat{s}_j \cdot \mathbf{r}_{ij})}{r_{ij}^5} \right], \quad (3)$$

where $g = 2$ is assumed, the summation is carried over all spins in the lattice and $\mathbf{r}_{ij}$ is the radius-vector between i -th and j -th spins. The dipolar interaction is responsible for the anisotropy and magnetostatic interaction (see below). In specific nanoscaled systems, the dipolar interaction is also a source of frustration and effective exchange-like terms of higher orders in (1).

Phenomenological description

Key conclusions about the collective phenomena can be derived using symmetry considerations. The requirement to have a non-zero magnetic moment at lattice sites is assured by the broken time reversal symmetry in magnetic substances. The macroscopic properties of the substance are determined by its magnetic crystal symmetry group. In the simplest case, the magnetic moments within each unit cell are oriented parallel and such substances are referred to as ferromagnets, whose magnetization M (magnetic moment per small enough volume) is non-zero. The unit cell may contain several ions with opposite orientations of moments, but still non-zero net moment (in a wide range of temperatures), which is called as the ferrimagnetic ordering. One says, that such ions belong to the different (magnetic) sublattices. In many practical cases, ferri- and ferro- magnets can be described within the same theoretical and experimental frameworks. If the sublattices possess the same magnetic moments and the crystal symmetry group contains the operation of their exchange, such a substance is referred to as the antiferromagnet. The influence of relativistic

interactions gives rise to a more detailed classification based on more complex ground states such as weak ferromagnets (canted antiferromagnets) and helimagnets to name a few.

A magnetic ordering typically appears below a critical temperature T_c (Curie and Néel temperature for ferro- and antiferromagnets, respectively). A simple (qualitative, but not quantitative) explanation of the respective phase transition is given by the Landau theory. In the vicinity of T_c , the free energy potential Φ can be written as a power series of the order parameter μ : $\Phi = \Phi_0 - a\mu^2 + b\mu^4 + \dots$ with $a \geq 0$ and $b > 0$. Assuming that $a = a_0(T_c - T)$ and vanishes above T_c , this provides an equilibrium value of $\mu(T < T_c)$. For ferromagnets, one can choose $\mu = |M| \equiv M_s$ with M_s being the saturation magnetization. In antiferromagnets, the length of the Néel vector L (staggered sum of different sublattices also called as the vector of antiferromagnetism) can be chosen as μ . More accurate and material-related description of phase transitions is provided by the renormalization group theory (see below). Within the classical approach, the reduction of the saturation magnetization with temperature for a Heisenberg magnet (1) is described by the Bloch law $M_s(T)/M_s(0) = 1 - (T/T_c)^{3/2}$.

Far below T_c , it is reasonable to expand the free energy into power series of components of the unit vector $\mathbf{n}$, which is aligned with the vector order parameter $\mathbf{M}$ or $\mathbf{L}$, and its spatial derivatives assuming that the spatial variations are small enough. The concrete form of the energy is determined by the relevant local and non-local interactions. Their classification is based on the range of spatial "sensitivity". The energy density of a local interaction is a function of the position at the given point $\mathbf{r}$ only. The non-local interactions make the torque, which acts on the $\mathbf{n}(\mathbf{r})$, being dependent on the state of other areas far from $\mathbf{r}$.

There are substances, which should be characterized by more than one order parameter at some conditions. An antiferromagnet with N sublattices in addition to $\mathbf{L}$ always can be characterized by the total magnetization $\mathbf{M}$ and $N-2$ additional vectors of antiferromagnetism as the secondary order parameters. However, for the macroscopic description, it is enough to use up to three vector order parameters (Andreev and Marchenko, 1980). Their relevance is determined by the crystal symmetries, spatial distribution of $\mathbf{L}$ and external influences. For example, weak ferromagnet Fe_2O_3 is characterized by non-zero $\mathbf{L}$ and $\mathbf{M}$, while triangular antiferromagnet Mn_3Ir has two vectors of antiferromagnetism of almost equal length in equilibrium. The crystal symmetry can allow additional terms in free energy, which are related to magnetoelectric or magnetoelastic effects, for example, $\Phi_{\text{me}} = -\alpha_{ij}H_iE_j$ (Cr_2O_3) or $\Phi_{\sigma} = -\beta_{ijk}\sigma_{ij}H_k$ (FeCO_3), respectively. Here, E is the electric field, σ_{ij} is the stress tensor, α_{ij} and β_{ijk} are magnetoelectric and magnetoelastic tensors, respectively (Glinchuk et al., 2013). In a particular case of antiferromagnet with equivalent sublattices, the presence of the center of symmetry in the crystallographic group of the given medium allows for a weak ferromagnetism and piezomagnetism and forbids the linear magnetoelectric effect, while the center of antisymmetry makes the picture to be opposite (Turov, 1994).

Local magnetic interactions

Micromagnetic framework describes the magnetic behavior at sub-micrometer scale, but far from the atomistic scale. In this respect, micromagnetism is macroscopic theory (Brown Jr, 1963). Within the micromagnetic framework, the exchange interaction for a ferromagnetic material with one magnetic sublattice has the energy density

$$w_x = (\nabla \mathbf{n}_i)(\nabla \mathbf{n}_i) \equiv -A \mathbf{n} \cdot \nabla^2 \mathbf{n}, \quad (4)$$

where $A \propto J$ is the exchange stiffness and ∇ is the gradient operator.

In multisublattice magnets, the exchange energy density can be formulated in terms of individual sublattice magnetizations, or all relevant order parameters, with the only difference in the definition of phenomenological constants (Turov, 1965). For example, for tetragonal crystals the relevant model considers two sublattices, whose local directions characterized by the unit vectors of magnetization $\mathbf{m}^a(\mathbf{r})$ and $\mathbf{m}^b(\mathbf{r})$. In this case, the exchange energy density reads

$$\begin{aligned} w_x &= \frac{A_1}{2} [(\nabla \mathbf{m}_i^a)(\nabla \mathbf{m}_i^a) + (\nabla \mathbf{m}_i^b)(\nabla \mathbf{m}_i^b)] + A_2 (\nabla \mathbf{m}_i^a)(\nabla \mathbf{m}_i^b) + \frac{\Lambda}{2} \mathbf{m}^a \cdot \mathbf{m}^b \\ &\equiv \Lambda \mathbf{m}^2 + A (\nabla \mathbf{n}_i)(\nabla \mathbf{n}_i), \end{aligned} \quad (5)$$

where Λ characterizes the so-called uniform exchange, $A = A_1 - A_2$ and the relations $\mathbf{m} = (\mathbf{m}^a + \mathbf{m}^b)/2$, $\mathbf{n} = (\mathbf{m}^a - \mathbf{m}^b)/2$ are used (Bogdanov et al., 2002). The terms containing gradients in the exchange energy density are referred to as the inhomogeneous exchange. For spin chains in a continuum limit, w_x should be complemented by the lifting term $w_{\text{lif}} = \lambda \mathbf{m} \cdot \mathbf{n}'$ with prime indicating the derivative along the chain, which is responsible for the ferromagnetic response of non-collinear textures (e.g., domain walls, see Section "Topological magnetic textures") (Papanicolaou, 1995), and geometry-induced weak ferromagnetism in curvilinear geometries (Pylypovskiy et al., 2021), see also Section "Curvilinear nanoarchitectures". In quantum spin chains, the presence of w_{lif} leads to the difference between systems with integer and half-integer spins.

The presence of relativistic interactions leading to the anisotropy of magnetic properties can be taken into account by the expansion of the energy density in the form

$$w_a = K_{ij}n_i n_j + K_{ijkl}n_i n_j n_k n_l + \dots \quad (6)$$

The anisotropy tensors K are symmetric. Their structure is determined by the crystal symmetry. For example, for a uniaxial easy axis magnet, $w_a = K_a(n_x^2 + n_y^2)$ with $K_a > 0$. This case is typical for interfacial anisotropy in Co/Pt or Co/Pd multilayers resulting in the easy axis of magnetization along z axis, which is perpendicular to the interface and is referred to as perpendicular magnetic anisotropy (PMA). Materials revealing PMA are relevant for magnetic data storage applications as media for hard disk drives (Varvaro and Casoli, 2016) and in spinorbitronics for magnetic random access memories (Cao et al., 2020). The anisotropy energy of magnets

with cubic symmetry (e.g., iron) reads $w_a = K_c(n_x^4 + n_y^4 + n_z^4)$. In the simplest case, $K_a \propto D$ and can incorporate, e.g., magnetostrictive effects (effects, related to the interplay between the magnetic subsystem and elastic distortions of the crystal lattice, see also Section “Phenomenological description”), interaction of neighboring dipoles and anisotropy of the exchange integral J .

The broken inversion symmetry of the environment of magnetic ions (e.g., B_{20} type alloys like MnSi or thin-film interfaces like Co/Pt multilayers) leads to the appearance of energy terms in the form of the Lifshitz invariants, $\mathcal{L}_{ij}^k = n_i \partial_k n_j - n_j \partial_k n_i$, where ∂_k represents a partial derivative over k -th spatial direction. The respective energy w_{DMI} contribution was first considered in Dzyaloshinskii (1964) and Dzyaloshinski (1965), and the microscopic mechanism was proposed by Moriya (1960) (Dzyaloshinskii-Moriya interaction, DMI). Among the relevant DMI terms, there is the energy of interfacial type, $w_{\text{DMI}}^{\text{I}} = D^{\text{I}} \mathbf{n} \cdot [(\mathbf{z} \times \nabla) \times \mathbf{n}] = D^{\text{I}}[(\mathbf{n} \cdot \nabla)n_z - n_z(\nabla \cdot \mathbf{n})]$, with the interface normal along z (e.g., asymmetrically sandwiched ultrathin Co films and crystals of C_{nv} symmetry class), and the energy of bulk-like type $w_{\text{DMI}}^{\text{B}} = D^{\text{B}} \mathbf{n} \cdot [\nabla \times \mathbf{n}]$ (crystals of T and O symmetry classes). Note, that the sign of D^{I} is a matter of convention. In antiferromagnets, this type of DMI is referred to as the inhomogeneous DMI in line with the exchange interaction. DMI is responsible for the stabilization of chiral bubbles and skyrmions, see Section “Skyrmions and magnetic bubbles”.

The crystal structure can allow next-neighbor exchange interactions and frustration, which are often of importance for single-layer films. Within the phenomenological approach, this is reflected in the appearance of energy density terms with higher order of spatial derivatives and their powers, e.g. $(\partial_{zz}^2 n_z)^2$ (c.f. w_x), which were studied in Michelson (1977b), Michelson (1977a) and Michelson (1977c). Both, Dzyaloshinskii and Michelson terms can lead to non-collinear ground states (the order parameter is not homogeneous in space). For multisublattice substances, the free energy density can contain terms, which mix components of the order parameters. For example, the term

$$w_{\text{wf}} = D_{ij} M_i L_j \quad (7)$$

with D_{ij} being the Dzyaloshinskii tensor, is responsible for the weak ferromagnetism. Weak ferromagnetism describes the appearance of the spontaneous ferromagnetic moment in antiferromagnets, which is much smaller than the sublattice magnetization, e.g. in α - Fe_2O_3 (Dzyaloshinskii, 1957; Moriya, 1960). As for the exchange, this term is referred to as the homogeneous DMI.

The competition between the exchange and other interactions introduces characteristic length scales. Depending on the dominant interactions, these length scales characterize the spatial inhomogeneity of a magnetic texture. For instance, the magnetic length $\ell = \sqrt{A/K}$ characterizes the spatial extension of a texture for the case of anisotropic magnetic material (the anisotropy constant can include magnetocrystalline, interfacial and shape anisotropy contributions, see Section “Non-local magnetic interactions”). The quantity $\ell_D = 8\pi A/D$ determines the period of the Dzyaloshinskii cycloid in helimagnets.

Non-local magnetic interactions

The state of a magnetic nanostructure is significantly influenced by the magnetic fields produced by the nanostructure itself. The short-range part of the dipolar field of individual magnetic moments (3) can be accounted for as a contribution to anisotropy (Section “Local magnetic interactions”). The long-range part is described by the solution of the magnetostatic Maxwell equations giving the stray field $\mathbf{H}_d = -\nabla \phi_d$ and the respective energy

$$E_d = -\frac{1}{2} \int \mathbf{M} \cdot \mathbf{H}_d d\mathbf{r}. \quad (8)$$

The magnetostatic potential ϕ_d is a sum of the volume and surface integrals of the so-called volume and surface magnetostatic charges $\lambda_d = -\nabla \cdot \mathbf{M}$ and $\sigma_d = \mathbf{v} \cdot \mathbf{M}$, respectively, where $\mathbf{v}$ is the sample's surface normal. The magnetostatic energy E_d is responsible for the formation of domains (regions with a spatially uniform $\mathbf{n}(\mathbf{r})$) in ferromagnets (see Sections “Single domain particles” and “Topological magnetic textures”) and, usually, is less relevant for the global state of antiferromagnets. There are special cases, when magnetostatics can be reduced to the effective anisotropy. In particular, a thin extended ferromagnetic film (planar or curved) with normal $\mathbf{v}$ possesses an effective anisotropy $w_a = K_d^{\text{shell}}(\mathbf{n} \cdot \mathbf{v})^2$ and $K_d^{\text{shell}} = \mu_0 M_s^2/2$ with μ_0 being the vacuum magnetic permeability. The subindex “d” refers to the shape anisotropy originating from the long-range dipolar interaction. For a thin ferromagnetic wire with a circular cross-section, the easy axis of magnetization follows its tangential direction with the effective anisotropy coefficient $K_d^{\text{wire}} = \mu_0 M_s^2/4$. Depending on the relation between K_d and K_a , ferromagnets are classified as soft (magnetostatics dominates) and hard (the intrinsic anisotropy is strong). The exchange length $\ell_x = \sqrt{2A/(\mu_0 M_s^2)}$ characterizes the spatial extension of a texture for the case of magnetically soft material like Permalloy (c.f. the magnetic length in Section “Local magnetic interactions”). For materials with PMA, the relation between the shape and magnetocrystalline anisotropy is quantified by the quality factor $Q_{\text{PMA}} = K_a/K_d$, which is relevant for skyrmion- and magnetic bubble-hosting materials, see Section “Skyrmions and magnetic bubbles”.

For ferro- and antiferromagnets, the magnetostriction can significantly alter the global state, being important if the deformation of different parts of the inhomogeneously magnetized body do not fit together. In particular, the minimization of the interaction energy of elastic dipoles can cause formation of domains in antiferromagnets.

Micromagnetic equations of state

Far below T_c , the temporal evolution of the order parameter $\mathbf{n}$ in ferromagnets is described by the Landau-Lifshitz equation (Landau and Lifshitz, 1935) supplemented by additional torques.

$$\dot{\mathbf{n}} = -\gamma_0 \mathbf{n} \times \mathbf{H}^{\text{eff}} + \mathbf{T}_{\text{rel}} + \mathbf{T}. \quad (9)$$

Here, overdot is the derivative with respect to time, $\gamma_0 > 0$ is the gyromagnetic ratio, $\mathbf{H}^{\text{eff}} = -(1/M_S)\delta\Phi/\delta\mathbf{n}$ is the effective field with δ being the variational derivative, and torques $\mathbf{T}_{\text{rel}}$ and $\mathbf{T}$ describe the magnetic relaxation and other contributions, respectively. Elastic and other degrees of freedom are not taken into account. For antiferromagnets, a convenient approach is to write a system of coupled Eq. (9) for each of sublattice magnetizations, which allows to derive the equation of motion for $\mathbf{L}$ as well. For antiferromagnets close to T_c , the equations of motion based on the Onsager relations can be of relevance.

The equilibrium magnetic state is determined by zero net torque acting on $\mathbf{n}$ or, alternatively, by zero variation of the energy. In a general case, the variation of energy allows to determine the boundary conditions, which supplement the equation of motion (9). For the particular case of the DMI w_{DMI}^b and presence of the surface anisotropy with the energy density w_{surf} , the boundary conditions read

$$\mathbf{n} \times \left[2A(\boldsymbol{\nu} \cdot \nabla)\mathbf{n} + f_{\text{DMI}}^{\text{bc}}(\mathbf{n}, \boldsymbol{\nu}) + \partial w_{\text{surf}} / \partial \mathbf{n} \right] = 0, \quad (10)$$

where $f_{\text{DMI}}^{\text{bc}}(\mathbf{n}, \boldsymbol{\nu}) = -D^b \boldsymbol{\nu} \times \mathbf{n}$ for the DMI of bulk type, and $f_{\text{DMI}}^{\text{bc}}(\mathbf{n}, \boldsymbol{\nu}) = D^i [\mathbf{z}(\boldsymbol{\nu} \cdot \mathbf{n}) - \mathbf{n}_z \boldsymbol{\nu}]$ for the DMI of interfacial type with $\mathbf{z}$ being the normal to the interface.

The relevant relaxation mechanism expressed in $\mathbf{T}_{\text{rel}}$ is dependent on the temporal scales. Considering a slow enough dynamics, a common approach is to utilize the relaxation term in the Gilbert's form $\mathbf{T}_{\text{rel}}^G = \alpha_G \mathbf{n} \times \dot{\mathbf{n}}$, which is derived within the Lagrangian formalism and conserves $|\mathbf{n}| = 1$. Note, that the relaxation term introduced by Landau and Lifshitz (1935) based on symmetry reasons coincides with the Gilbert's one up to rescaling of γ_0 in (9) and α_G . For the case of ultrafast dynamics or finite temperatures, the longitudinal relaxation of $\mathbf{M}$ becomes relevant (Atxitia et al., 2017), which is taken into account in the relaxation terms of Bar'yakhtar $\mathbf{T}_{\text{rel}}^{\text{Bar}} = \lambda_1 \mathbf{H}^{\text{eff}} - \lambda_2 \nabla^2 \mathbf{H}^{\text{eff}}$ and Bloch $\mathbf{T}_{\text{rel}}^{\text{Bl}} = \alpha_{\parallel} (\mathbf{M} \cdot \mathbf{H}^{\text{eff}}) \mathbf{H}^{\text{eff}} - \alpha_{\perp} \mathbf{M} \times [\mathbf{M} \times \mathbf{H}^{\text{eff}}]$, respectively, where $\lambda_{1,2}$ and $\alpha_{\parallel,\perp}$ are some constants. Note that in this case, Eq. (9) should be written explicitly for $\mathbf{M}$ instead of the unit vector $\mathbf{n}$.

Additional torques in Eq. (9) can originate due to (i) spin-orbit coupling (Han et al., 2021; Shao et al., 2021) and (ii) spin-transfer effects (Baraduc et al., 2010). They allow to alter magnetic textures, e.g., reorient the magnetization in a thin, soft magnetic layer lying on a hard magnet or induce its precession, an even induce spin-wave instabilities.

- (i) The spin-orbit torque can be exerted due to the spin accumulation at the ferromagnet-heavy metal (Pt or Au) interface. Independently of their nature (e.g., spin Hall or Rashba effect), they can be classified by their symmetry: antidamping or field-like torques, $\mathbf{T}_{\text{ant}} \propto \mathbf{n} \times [\boldsymbol{\mathcal{S}} \times \mathbf{n}]$ or $\mathbf{T}_f \propto \mathbf{n} \times \boldsymbol{\mathcal{S}}$, respectively. Here, $\boldsymbol{\mathcal{S}} = \mathbf{j} \times \mathbf{z}$ with $\mathbf{j}$ being the current density, which creates the electric field, and $\mathbf{z}$ being the normal directions to the multilayer stack.
- (ii) For spin-transfer effects, the spin angular momentum is transferred from one metallic magnet to another one. The Slonczewski mechanism (Slonczewski, 1996; Berger, 1996; Slonczewski, 2002) is relevant for multilayer structures, where the electric current $\mathbf{j}$ flows perpendicularly to the interface (CPP, current perpendicular-to-plane geometry) leading to the torque $\mathbf{T}_S \propto \mathbf{n} \times [\mathbf{n} \times \mathbf{j}]$ (c.f. $\mathbf{T}_{\text{ant}}$). Here, the coefficient of proportionality is determined by the degree of polarization of current electrons, which flow through the polarizing magnetic layer with strong anisotropy, and alignment of the magnetization of the target magnet $\mathbf{n}$ with the current flow direction. If the electric current flows along the magnetic nanostructure (CIP, current-in-plane geometry), conducting electrons can be polarized as well, and their interaction with the magnetic texture is described by the torque of Zhang and Li (2004) and Bazaliy et al. (1998), $\mathbf{T}_{\text{ZL}} \propto \mathbf{n} \times [\mathbf{n} \times (\mathbf{j} \cdot \nabla)\mathbf{n}] + \beta_{\text{ZL}} \mathbf{n} \times (\mathbf{j} \cdot \nabla)\mathbf{n}$, where β_{ZL} is the nonadiabatic spin-transfer parameter.

Critical phenomena

The rigorous treatment of the behavior of $\mathbf{n}$ in the vicinity of the phase transition from the magnetically ordered to the paramagnetic state needs to account for thermal fluctuations, whose influence becomes decisive near T_c . This is addressed by the renormalization group theory. Within this approach, changes of physical quantities just below T_c are described in terms of power laws with the variable $t = T/T_c - 1$ with the so-called critical exponents. The main scaling laws introduce six critical exponents α , β , γ , δ , η and ν considering the specific heat $C \sim |t|^{-\alpha}$, spontaneous magnetization $M_S \sim |t|^{-\beta}$, susceptibility $\chi \sim |t|^{-\gamma}$, relation between the field and magnetization $H \sim M_S^\delta$, correlation function $\Gamma(x) \sim x^{2-d-\eta}$ with d being the system's dimension (e.g., $d = 1$ for a chain), and correlation length $\xi \sim |t|^{-\nu}$. In the vicinity of T_c , the exponents obey equalities (scaling laws) $\alpha + 2\beta + \gamma = 2$ (Rushbrook), $\gamma = \beta(\delta - 1)$ (Widom), $\gamma = (2 - \eta)\nu$ (Fisher) and $d\nu = 2 - \alpha$ (Josephson). The scaling laws allow to deduce all the critical exponents by knowledge of two of them. For a pure Nickel, $\beta \approx 0.42$ and $\gamma \approx 1.314$. The magnet, which is described by the Heisenberg Hamiltonian (1) only ($d = 3$), has $\beta \approx 0.313$ and $\gamma \approx 0.37$. Note, that the presence of long-range interactions alters the critical exponents.

The critical behavior is considered to be universal, in the sense that it is the same for different materials if they possess the same intrinsic symmetries independently of their electronic structure. The universality is observed far from T_c as well. For example, the sublattice magnetization $M_S \propto 1 - (T/T_c)^2$ for EuTe and $\text{Y}_3\text{Fe}_5\text{O}_{12}$ (cubic magnets with half-integer spin), and $M_S \propto 1 - (T/T_c)^3$ for Cr_2O_3 and NiO (axial magnets with integer spin) for low enough temperatures.

A central role of the symmetry (which, in addition to the unit cell structure, is determined by d and the number of free spin components N_{sp}) is revealed by the Ising model. The Ising model itself allows the only one degree of freedom of the spin vector $\mathbf{s}$

(e.g., along z axis, $N_{sp} = 1$) with the Hamiltonian $\mathcal{H}_I = -J \sum_{i,j} s_i^z s_j^z$ (c.f. (1)) with summation over neighboring spins. For a chain with $d = 1$, the Ising model is in the ordered state only at $T = 0$. The temperature driven phase transitions become possible for $d > 1$. Among extensions of the Ising model, one can mention the XY model with $N_{sp} = 2$ (the only $s^z \equiv 0$), the ANNNI model (axial next-nearest neighbor Ising), which allows competing exchange interactions and the Potts model, which introduces intrinsic states to govern the interaction between spins.

Single domain particles

The field H_d can be uniform within a solid sample of the ellipsoidal shape, and its limiting cases (wires and thin films) leading to the possibility of $n = \text{const}$ within the sample as well. This does not guarantee that this state has the minimal energy if the sample's dimensions are large enough. Uniformly magnetized particles is a convenient theoretical abstraction, which allows to understand physics of the magnetization reversal of magnetic nanostructures without involved mathematical analysis. The corresponding theory was formulated by [Stoner and Wohlfarth \(1948\)](#).

In the following, we consider criteria of nanoobjects to be in the single domain state (Sections “Single domain particles” and “Nonuniform nontopological magnetization patterning”), collective superparamagnetic behavior of such nanoparticles (Section “Superparamagnetism”), and their magnetization reversal in magnetic fields (section Stoner-Wohlfarth model).

Single domain particles

The critical radius of a spherical particle is defined when the energy of a domain wall spanning a spherical particle is equal the change of the magnetostatic energy for a single- and two-domain states:

$$D_{s-\text{dom}} = \frac{72\sqrt{AK_a}}{\mu_0 M_s^2} \quad (11)$$

For hard magnetic materials like FePt alloy, the critical single domain diameter of a spherically-shaped particle is 340 nm. For soft magnetic materials like Fe_3O_4 , the critical size is in the range of 12 nm only.

Superparamagnetism

As in any ferroic material, long-range ordering in magnetic materials is present below a critical temperature, which is known as Curie temperature for ferro- and ferrimagnets and Néel temperature for antiferromagnets. The transition from the magnetically ordered to magnetically disordered state is the magnetic phase transition. For instance, the Curie temperature for FePt alloy is 750 K. When the size of the ferromagnetic material is decreased below a certain critical one, the magnetic moment of the particle averaged over the measurement time of the experiment can become reduced effectively to zero. As a result, at long time scales (measurement time is longer than the relaxation time of the magnetization) the particle behaves as a paramagnet although it remains magnetically ordered. Application of an external magnetic field results in a much stronger magnetic response than would be the case for a paramagnet. The relaxation time is given by the Arrhenius law $\tau = \tau_0 \exp(-E_B/k_B T)$. The energy barrier $E_B = K_a V$ is given by the anisotropy energy of the magnetic particle of volume V with the anisotropy constant K_a . Here, τ_0 is the natural lifetime characterizing the attempt frequency for the magnetization reversal typically taken as 10^{-9} s, which is of the order of magnitude of the frequency of the ferromagnetic resonance. The relaxation time τ should be compared to the typical measurement time, which is strongly dependent on the experimental setup. For instance, for the measurement of the magnetic moment using a conventional superconducting quantum interference devices (SQUIDS), the measurement time is in the range of 10 s. When using nuclear magnetic resonance (NMR), the characteristic time is in the range of 10^{-6} s. The superparamagnetic critical diameter for a spherical particle is given by a volume $V = \ln(\tau/\tau_0) \times k_B T / K_a$. This equation allows to determine the minimal size of magnetic nanoparticles for their stability at the given temperature for given time. This is especially useful for the determination of the stability of the written bit of information in magnetic data storage. For instance, if we request that the individual magnetic nanostructure with $K_a = 1 \text{ MJm}^{-3}$ should be stable over 10 years at $T = 300$ K, then the diameter of this nanostructure should be in the range of 7 nm, which can be achieved using for instance hard magnetic FePt alloys. Alternatively, it is possible to solve the relaxation equation with respect to temperature $T_B = \ln(\tau/\tau_0) K_a V / k_B$, which provides access to the transition temperature when the magnetic nanoparticles with the volume V and anisotropy constant K_a will experience transition to the superparamagnetic regime for the case when the magnetic moment is measured with a characteristic time τ . The transition temperature to the superparamagnetic regime is called blocking temperature. For a FePt nanoparticle ($K_a = 1 \text{ MJm}^{-3}$) with a diameter of 4 nm, the blocking temperature is about 110 K, which is substantially lower than the Curie temperature of the FePt alloy.

The magnetization of an ensemble of superparamagnetic particles measured at temperature T in a magnetic field H applied along z -axis is described via Langevin function: $M_z = M_s [\coth(x) - 1/x]$ with $x = \mu_0 M_s V H / (k_B T)$.

The interaction between nanoparticles embedded in a matrix can change the Langevin-like behavior of $M_z(H, T)$. For example, Fe nanoparticles embedded in Au create exchange-coupled clusters, which can be taken into account by replacing the temperature $T \rightarrow T + T^*$ with T^* being the interaction parameter ([Binns et al., 2002](#)). Beyond the so-called percolation threshold, the entire system of nanoparticles can be considered as the exchange-coupled medium with the random direction of the anisotropy axis within each particle. Its properties are determined by the correlation function of the anisotropy axes.

Stoner-Wohlfarth model

For the case of a homogeneously magnetized particle with easy axis anisotropy, it is possible to describe the magnetization reversal process analytically. This situation is applicable for an ellipsoid-shaped particles, where the magnetization switches homogeneously (all moments are parallel during the reversal process). The corresponding model, which takes into account the anisotropy energy, magnetostatic energy and Zeeman energy was solved by [Stoner and Wohlfarth \(1948\)](#). This model allows to calculate the coercive and nucleation fields for the magnetization reversal. For instance, when the magnetic field is applied along the easy axis of magnetization, the coercive field is $H_c = 2K_{\text{eff}}/\mu_0 M_s$, where K_{eff} includes the uniaxial magnetocrystalline and shape anisotropies. The anisotropy field is defined as the smallest field, which should be applied to switch magnetization. Without demagnetizing fields, the anisotropy field is $H_{\text{an}} = 2K_a/\mu_0 M_s$. The coercive field for the magnetization reversal decreases with the increase of temperature, $H_c = 2K_a/(\mu_0 M_s) \times [1 - \sqrt{\ln(\tau/\tau_0) \times k_B T / (K_a V)}]$. The switching field is dependent on the angle between the magnetic field and the easy axis of magnetization ψ . For a Stoner-Wohlfarth particle, the angular dependence of the switching field is given by the expression, $H_{\text{sw}} = H_{\text{an}}/(\sin^{2/3}\psi + \cos^{2/3}\psi)^{3/2}$. In contrast to the coercive field, which is usually defined as the field at which the magnetization is zero ($M = 0$), the switching field corresponds to the field of the steepest change of the magnetization with respect to field (maximum of $|dM/dH|$). This angular dependence is representative for the reversal of individual nanostructures representing bits of information in magnetic bit patterned media. We note that the Stoner-Wohlfarth angular dependence is different from the one derived by [Kondorsky \(1937\)](#) for the case of nucleation and domain wall propagation, $H_{\text{sw}}^K \propto 1/\cos\psi$. For the ensemble of Stoner-Wohlfarth particles with random orientation of the easy axis of magnetization, the resulting magnetization of the ensemble is $M_s/2$ and the coercive field $H_c = 0.48H_{\text{an}}$.

Nonuniform nontopological magnetization patterning

If the particle's lateral dimensions are of the order of the single-domain size, but the shape is not ellipsoidal, the strictly uniform state is impossible. This is reflected in a slight divergent distortion of the magnetization at the sample's ends, which is referred to as the flower state. The intermediate lateral sizes between the single- and multidomain states lead to the strongly inhomogeneous states, such as S- or C-states named according to the shape of the magnetization flow. In a general case, the magnetostatic interaction leads to the appearance of a domain structure.

Topological magnetic textures

Beyond the single-domain limit of nanoparticles (also for thin films, shells and bulk magnets), the order parameter $\mathbf{n}(\mathbf{r})$ can be characterized by the absence or presence of specific topological features, which are related to the vector nature of $\mathbf{n}$ only. This provides a powerful complementary approach relying on the topology to understand inhomogeneous spatial distributions of $\mathbf{n}$, which are referred to as magnetic textures and can be of high complexity. The introduction to the topology and its application to magnetism is given in Section "Magnetic topological solitons". For instance, relying on purely topological considerations, it is possible to predict the allowed magnetic states, e.g. in spherical geometries, where the hairy ball theorem forbids strictly tangential ordering without singularities ([Kravchuk et al., 2012](#)), or domain walls structure supported by a magnetic Möbius ring ([Pylypovskiy et al., 2015](#)). Non-trivial topological features in $\mathbf{n}(\mathbf{r})$ -field are related to the stability of the respective textures, which is important for their application potential. In the following, one-dimensional (Section "Domain walls"), two-dimensional (Sections "Magnetic vortices" and "Skyrmions and magnetic bubbles"), and three-dimensional (Section "3D textures") magnetic textures with non-trivial topology are considered.

Magnetic topological solitons

A competition between the exchange and anisotropic (anisotropy itself or/and magnetostatics) or helimagnetic (next-neighbor exchange, DMI) interactions can stabilize spatially inhomogeneous magnetic textures (the distribution of the order parameter $\mathbf{n}(\mathbf{r})$). If the particular distribution connects regions in the locally ground state (e.g., along the anisotropy axis), there is no continuous transformation of $\mathbf{n}(\mathbf{r})$ into the global ground state, which is in contrast to magnetic states mentioned in Section "Nonuniform nontopological magnetization patterning". Such magnetic texture is referred to as a topological magnetic soliton ([Kosevich et al., 1990](#); [Gobel et al., 2021](#)). Note, that there are localized solitary solutions of Eq. (9), which are stabilized by dynamics instead of topological reasons.

The topological properties of a given texture can be described by the mapping of the physical space onto the space $\mathbb{R}_{\text{op}}$ of the order parameter $\mathbf{n}$ ([Mermin, 1979](#)). The latter can be represented, e.g., by a unit circle $\mathbb{S}^1$ or sphere $\mathbb{S}^2$ (Bloch sphere) for the planar and three-dimensional configurations, respectively. Often, the mapping itself can be described by the first or second homotopy groups $\pi_1(\mathbb{R}_{\text{op}})$ (map of closed loops is relevant for domain walls and vortices, see Sections "Domain walls" and "Magnetic vortices", respectively) or $\pi_2(\mathbb{R}_{\text{op}})$ (map of spheres,¹ is relevant for skyrmions and vortices, see Sections "Skyrmions and magnetic bubbles" and "Magnetic vortices", respectively). Then, each topological soliton can be characterized by the degree of mapping (also referred to as topological index or charge), which reflects a number of windings made by $\mathbf{n} = \{\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta\}$ between the connected ground states.

¹In the sense of topology, plane and sphere are equivalent.

The $\pi_1(\mathbb{S}^1)$ charge can be introduced as $Q_1 = \int \theta' ds / (2\pi) = \int d\theta / (2\pi)$, where s is the coordinate along which the magnetic polar angle θ varies keeping $\phi = \text{const}$. For the case of a single domain wall (topological charge p in Section “Domain walls”), $Q_1 = \pm 1$. For merons (Section “Magnetic vortices”), Q_1 calculated for ϕ along the closed loop corresponds to the so-called vorticity.

The Pontryagin index

$$Q = \frac{1}{8\pi} \int \mathbf{n} \cdot [\partial_x \mathbf{n} \times \partial_y \mathbf{n}] dx dy \equiv \frac{1}{4\pi} \int \sin \theta d\theta d\phi \quad (12)$$

characterizes the mapping $\pi_2(\mathbb{S}^2)$ and, by absolute value, says how many times $\mathbf{n}$ covers the unit sphere. Concerning curvilinear shells, one should take into account the topology of the shell itself, which is given by the surface' genus g defining the normal Gauss map $Q_G = \mp(1 - g)$. In this way, the normally magnetized sphere can be referred to as the object in the topologically trivial state with the actual topological index $Q' = Q - Q_G = 0$ (Kravchuk et al., 2016).

The topology of 3D textures is characterized by the homotopy group $\pi_3(\mathbb{S}^2)$, i.e., mapping of a 3-sphere² onto a unit sphere covered by $\mathbf{n}(\mathbf{r})$. It is characterized by the Hopf index

$$\mathcal{H} = \frac{1}{16\pi^2} \int \varepsilon_{ijk} \varepsilon_{\alpha\beta\gamma\delta} \tilde{n}_\alpha \frac{\partial \tilde{n}_\beta}{\partial x_i} \frac{\partial \tilde{n}_\gamma}{\partial x_j} \frac{\partial \tilde{n}_\delta}{\partial x_k} d^3x. \quad (13)$$

Here, tensors ε_{ijk} and $\varepsilon_{\alpha\beta\gamma\delta}$ are antisymmetric by all their indices, Greek indices enumerate components of the 4-dimensional vector $\tilde{\mathbf{n}} = \{\nu \sin X, \cos X\}$ with the unit vector $\nu \in \mathbb{R}^3$, and Latin indices run over Cartesian coordinates x, y, z . The order parameter reads $\mathbf{n} = z \cos 2X + 2\nu z \sin^2 X + [\nu \times z] \sin 2X$. Magnetic textures with different values of $\mathcal{H}$ are determined by the choice of functions $\nu(\mathbf{r})$ and $X(\mathbf{r})$.

Since Eq. (9) does not allow breaks of the continuous vector field $\mathbf{n}$, the topological index is a conserved quantity in an infinite system, which renders the topological solitons to be perspective information carriers of high stability. Besides boundaries, the conservation of the topological index can be violated by the effects of lattice discreteness and temperature.

A frequently used analytical way to describe topological solitons is the collective variable approach, which allows to reduce a system with infinite degrees of freedom to a few variables within the Lagrangian formalism. In particular, it can be a soliton position and phase of the order parameter as in $q - \Phi$ model (Slonczewski, 1973). A particular example of this approach is the Tiele equation for dynamics of ferromagnetic solitons (Thiele, 1973).

A seminal example of the topological soliton is presented by the Belavin-Polyakov solution in 2D for an isotropic ferromagnet (Belavin and Polyakov, 1975). In the cylindrical reference frame (ρ, χ, z) , the polar magnetic angle θ satisfies the relation

$$\tan \frac{\theta}{2} = \left(\frac{R}{\rho} \right)^{|Q|} \quad (14)$$

with R being the soliton radius, $Q \in \mathbb{Z} \setminus \{0\}$ characterizing the degree of $\pi_2(\mathbb{S}^2)$ map and arbitrary in-plane phase $\phi_0 = \phi - Q\chi$. The radius R is not defined in the exchange approximation (the soliton collapses to the line defect in $\mathbf{n}$) and needs other interactions for stabilization of the soliton according to the Derrick-Hobart theorem in case of the absence of higher-order spatial derivatives.

Domain walls

The region between two magnetic domains is called a domain wall (DW). DWs are classified by their symmetry, which is determined by the symmetry of the energy functional. In the simplest case, the transition region can be characterized by an axis of propagation, perpendicular to this region. An achiral uniaxial magnet with the easy axis along z direction supports 180° walls with $n_z = p \tanh(x/\Delta)$, where x axis is chosen as the propagation direction for clarity, $p = \pm 1$ is the topological charge and the wall width parameter $\Delta = \sqrt{A/K_a}$. The sense of rotation of $\mathbf{n}$ within the wall is determined by magnetostatics. In bulk samples, $\mathbf{n}$ rotates perpendicularly to the propagation direction to avoid volume magnetostatic charges (Bloch wall). In thin enough ferromagnetic films, the penalty due to the surface charges forces $\mathbf{n}$ to rotate along the propagation direction (Néel wall). The presence of DMI also favors the concrete DW type: w_{DMI}^b and w_{DMI}^i lead to the chiral DWs of the Bloch and Néel types, respectively, with the rotation direction of $\mathbf{n}$ inside them (clockwise or counter-clockwise) determined by the sign of $D^{\text{b,i}}$. The head-to-head (tail-to-tail) DWs in thin nanowires, stripes and tubes, which are named accordingly to the domains' magnetization, also belong to 180° walls family. The presence of higher-order anisotropies leads to the appearance of neighboring domains, where the order parameter rotates to lower angles, e.g., 90° walls in ferroelectric-ferromagnetic heterostructures or 71° and 109° walls in cubic magnets.

Magnetic nanostripes are prototypical examples of racetracks supporting the motion of topological solitons driven by external fields or torque T . Depending on the stripe thickness and width, the head-to-head DW structure can be more complex. For a thin achiral stripe, magnetostatics favors the symmetric transversal DW (magnetization rotates transversal to the stripe, in the stripe' plane). For a larger thickness, the DW becomes asymmetrically tilted and for a thick enough sample the domains are separated by the vortex DW (see below). Nanotubes of large enough diameter support the formation of vortex DWs as well with a circulation of $\mathbf{n}$ around the tube.

²3-sphere is an analog of a regular sphere with one more dimension and is topologically equivalent to the three-dimensional Cartesian space $\mathbb{R}^3$.

The DW dynamics is determined by the balance of the driving term and damping α . The DW velocity is proportional to the drive for a weak enough force up to the critical field (current) called the Walker limit. Above the Walker limit, the motion becomes oscillatory with the reduction of the average velocity.

Magnetic vortices

A vortex is the magnetic texture with in-plane closed circular flux of $\mathbf{n}$ in the vicinity of the origin. In a system with the cylindrical symmetry, its in-plane distribution reads $\phi = q\chi + \phi_0$, where $q \in \mathbb{N}$ is the vorticity ($\pi_1(\mathbb{S}^1)$ homotopy group), χ is the polar angle and ϕ_0 is the phase. Vortices are the ground states in magnetically soft nanodisks, whose radius is sufficiently large in comparison with thickness. Their stability is supported by the magnetostatics, which provides an effective anisotropy at the disk edge to avoid $\sigma_d \neq 0$ with $\phi_0 = C\pi/2$ and $C = \pm 1$ called circulation. A Gaussian-like out-of-plane magnetization in the vortex origin is referred to as the vortex core, with the polarity $p_{\text{vor}} = \pm 1$ depending on its co- or counter-directionality with respect to z -axis. The vortex core represents the Bloch line: a twist of the domain wall, which divides it onto oppositely magnetized parts (Guslienko, 2008; Gaididei et al., 2010). Vortex state is also characteristic for the ring-shaped objects, where for a sufficiently large internal radius the out-of-plane component is absent. Geometrical features as notches in magnetic rings allow to control the value of circulation C (Kläui et al., 2001).

Vortices possess half-integer topological charges $Q = p_{\text{vor}}q/2$ and, therefore, are classified as merons in the topological sense. Values of C and p_{vor} can be changed by external fields (strong enough static field or resonant switching by alternating fields) or currents. The presence of DMI alters the width of the vortex core (Butenko et al., 2009).

Depending on the nanodot size and shape of the boundary, magnetostatics can stabilize other states, e.g. the Landau structure, which is similar to vortex and is formed in square-shaped soft nanodots. In astroid-shaped particles, it is possible to form antivortices with $q \in \mathbb{Z}_-$. Vortex-antivortex pairs can be dynamically created during switching of the vortex polarity, instability of the saturated state or due to thermodynamic reasons (Berezinskii-Kosterlitz-Thouless transition for the XY model (Berezinsky, 1971; Berezinsky, 1972; Kosterlitz and Thouless, 1973)). Elongated soft nanodots of large enough size host a series of vortices and antivortices (the cross-tie state).

The magnetic textures with $|q| > 1$ are unstable in the absence of the next neighbor exchange interactions. The value of Q is one of the quantities determining the gyrotropical motion of vortices. The change of the vortex polarity, mediated by the dynamical appearance of vortex-antivortex pairs (Gaididei et al., 2010), or induction of vortex-antivortex superlattices by the spin-polarized current (Volkov et al., 2011) preserves the value of Q characteristic for the ground state of the nanodot. Planar as well as curvilinear nanodots in a vortex state can be arranged in arrays can possess higher susceptibility and lower critical fields due to the magnetostatic inter-dot interaction (Guslienko, 2008; Streubel et al., 2015a, 2015b; Streubel et al., 2016).

Skyrmions and magnetic bubbles

Magnetic materials with strong uniaxial anisotropy support topologically nontrivial textures with integer Q . The magnetostatics allows to stabilize circular DWs (cylindrical domains or magnetic bubbles) of Bloch type (e.g., some garnets like YIG and amorphous films based on GdCo). The presence of DMI select the energetically preferable rotation of $\mathbf{n}$ within the DW (chiral bubbles or skyrmion bubbles, e.g., in Ta/CoFeB/TaO_x). Circular DWs can host several Bloch lines, which influence their dynamic properties.

The DMI itself can stabilize skyrmions with $Q = \pm 1$, which have smaller radii than cylindrical domains (Co/Pt and Co/Pd asymmetric stacks, MnSi, Cu₂OSeO₃). They are characterized by a strong spatial localization and can be displaced using lower density electric current in comparison with DWs. Ferromagnetic skyrmions possess a Magnus-like force acting perpendicularly to the current direction (skyrmion Hall effect). It is canceled for two-sublattice antiferromagnetic skyrmions, leading to the straight propagation along the applied current.

Depending on the temperature and external magnetic field, applied along the anisotropy axis, skyrmions and magnetic bubbles can appear either as individual objects or in hexagonal lattices as the ground state. The specific DMI symmetry can lead to the appearance of antiskyrmions (e.g. in crystals of D_{2d} or S_4 symmetry classes).

Stable vortex-antivortex pairs in easy-plane magnets with DMI are also referred to as bimerons. They act as a skyrmion analog in the absence of a dominating easy axis. Equilibrium skyrmionic textures with $|Q| > 1$ are characteristic for frustrated magnets.

3D textures

Except cases of purely one- or two-dimensional magnets, like atom-by-atom engineered chains or van der Waals materials, and films of thickness much less than the magnetic length, magnetic textures can possess significant 3D non-uniformities. For the vortex state, this is reflected in a barrel-shaped distortion of the vortex core (narrow core at the surface and wide in a bulk). Skyrmions stabilized by the DMI of Bloch type form skyrmion lines through the magnetic medium, which can be of curved shape. Lattice defects can also stabilize curved domain walls in 3D (Donnelly et al., 2020).

Similarly to the fact, that the Bloch line can be understood as a twist of the domain wall, a twist of the Bloch line corresponds to the so-called Bloch point: a hedgehog-like 3D texture with a singularity in the center. Bloch point has properties of a magnetic monopole (an emergent electrodynamics in the solid state physics) with the singularity assured by the lattice discreteness or local reduction of M_s . In addition to the stabilization on Bloch lines, the Bloch point appears dynamically in processes of the vortex polarity switching and unwinding of skyrmion tubes. The skyrmion tube starting on the surface can be terminated by the Bloch point in equilibrium under certain conditions, forming the so-called magnetic bobbler.

Purely 3D topological solitons are represented by the Hopf solitons with non-zero Hopf index. In particular, they are characterized by magnetization distributions following torus-like configurations. As representative examples, one can consider a 3D vortex (often referred to as Hopfion) in the easy-axis magnet with the oppositely magnetized volume of toroidal shape (Kosevich et al., 1990), or vortex rings formed by the magnetization streamlines of the multiply stacked closed loop shape (Cooper, 1999). The stabilization of Hopfions in magnetic nanoparticles is possible via the next-neighbor exchange interactions with frustration and specific symmetries of DMI in finite samples.

Curvilinear nanoarchitectures

The role of the sample's shape in magnetism goes beyond shape-induced patterning such as flower states or vortices. For example, bound of the vector field $\mathbf{n}$ to a shell maps the topological properties of the latter onto the behavior of $\mathbf{n}$. For the case of a magnetically soft sample of a spherical topology, this is reflected in the inability to have $\mathbf{n}$ strictly tangential to the shell, hence resulting in the presence of vortices as expected according to the hairy ball theorem.

The framework of curvilinear magnetism describes how the geometric and topological properties of the sample's shape affect the behavior of magnetic textures (Makarov et al., 2022; Sheka et al., 2022). In particular, curvilinear magnetism identifies magnetic responses and effects, which manifest themselves by the curvature κ and torsion τ of nanowires and principal curvatures $\kappa_{1,2}$ of thin shells, where the respective functions are calculated with respect to the "base"³ curve γ or surface σ . In the following, we introduce the key aspects of geometry within the micromagnetic framework in the energy functional (Section "Energy functionals"), spin torques in the Landau-Lifshitz Eq. (9) (Section "Torques in the Landau-Lifshitz equation"), and interplay between magnetic and mechanical degrees of freedom in mechanically soft magnets (Section "Mechanically ultrasoft magnets").

Energy functionals

Practically relevant examples when the anisotropy axis can be spatially inhomogeneous include: (i) shape anisotropy of thin wires leading to the uni- or biaxial anisotropy with axes depending on the position along γ if the wire's cross-section is circular or not; (ii) interface-induced anisotropy following the shell normal ν such as in Co/Pt multilayers; (iii) shape anisotropy of thin shells with the hard axis along ν . In comparison with a straight wire or extended film, this breaks the translational symmetry of the magnet. The symmetry can be locally restored by considering the properties of the magnet in the reference frame, which follows the anisotropy direction and, in the considered examples, the geometry of the sample. Methodologically, this means incorporation of the translationally invariant terms (including identification of the derivatives along the tangential directions) in the energy functional, while the rest terms turn out to be determined by $\kappa_{1,2}$ or κ and τ . The latter includes the appearance of the geometry-driven terms with symmetries of DMI and anisotropy stemming from the exchange and intrinsic (i.e., related to the lattice unit cell) DMI. The geometry-driven weak ferromagnetism and geometry-driven effects from anisotropy are present in curvilinear antiferromagnetic spin chains (Pylypovskyi et al., 2021).

The gradient of material parameters, including the geometry-driven ones, is a source of pinning and automotion of magnetic solitons. For example, the curvature maximum and strong gradient represent the pinning potentials due to the energy gain in the exchange. Therefore, in their vicinity, the change of the energy landscape induces the geometry-driven motion of domain walls and skyrmions (Yershov et al., 2018; Korniienko et al., 2020).

Torques in the Landau-Lifshitz equation

In thin enough wires, the current flow j follows the wire's shape. This makes the torque-driven dynamics geometry-dependent via the field-like or antidamping-like torques. For the domain wall motion imposed by T_{ZL} , this is reflected in the reduction of the non-adiabatic parameter by $\beta_{\text{ZL}}^* = p\tau\ell$ and respective modification of the Walker limit (Yershov et al., 2016).

Mechanically ultrasoft magnets

A ferromagnetic sample with small enough Young's modulus undergoes a mechanical deformation as the response on the equilibrium magnetic texture, which reflects the symmetry of the involved energy terms. For instance, the balance between the exchange and easy-axis anisotropy in rings results in the ring's shape of circular and biaxial oval symmetries. The presence of DMI supports twists and bends of ferromagnetic stripes (Gaididei et al., 2019; Yershov et al., 2019).

Materials and applications

Magnetic nanostructures can be prepared via chemical synthesis, direct writing or physical vapor deposition combined with lithographic patterning. Alternatively, nanosized particles can be prepared from powder with larger constituents upon appropriate processing. For instance, by hydrogen assisted processing, NdFeB microparticles can be processed in a powder with 300 nm large nanoparticles (Gutfleisch et al., 2002). These nanopowders of NdFeB are relevant for permanent magnet applications. The choice of the material for nanoparticles is determined by the target application. For magnetic data storage applications like bit patterned media concepts, ordered arrays of hard magnetic nanoparticles are needed. In this respect, much attention is dedicated to the realization of ordered arrays of hard magnetic monodisperse FePt nanoparticles with a size in the range of 3–10 nm (Sun, 2000).

³Under the "base" curve one means the curve, which can be extended into lateral dimension to coincide with the given wire. Similarly, the "base" surface is the surface, which can be extended into both directions along the surface normal to match the shape of the shell.

For medical applications, superparamagnetic and biocompatible particles are used like Fe_3O_4 . Their synthesis is well established, for instance, based on controlled co-precipitation techniques. There is an active research on the stabilization of magnetic particles in solutions. Coatings provide the stabilization to magnetic nanoparticles against aggregation in a biological medium and in a magnetic field. Furthermore, with the decrease of the particle size, the susceptibility of nanoparticles toward oxidation increases (Lu et al., 2007). There are many stabilizers including monomeric stabilizers (e.g., phosphates, and sulfates), polymers like dextran and chitosan, dendrimers etc. For instance, dendrimers have an added advantage of not only providing stability to the magnetic nanoparticles in solution but also help in binding various biological ligands to the surface of colloids (Dietrich et al., 2012). To achieve inorganic core-shell particles, it is possible to use different sol-gel approaches. For instance, sol-gel synthesis is employed to obtain silica-coated Fe_3O_4 ferrofluids using tetraethyl orthosilicate through its hydrolysis and condensation (Narayanan et al., 2011). Furthermore, magnetic nanoparticles generated much attention in different technologies, particularly, magnetic inks for ink-jet printing (Voit et al., 2003), biosensing (Miller et al., 2002; Chen et al., 2011), targeted drug delivery (Jain et al., 2005; Chourpa et al., 2005) and contrast agent in magnetic resonance imaging (MRI) (Boutry et al., 2006; Corot et al., 2006).

Core-shell particles and exchange bias effect

Core-shell nanoparticles could be composed of two magnetic materials including two ferromagnets, say magnetically hard in the interior (core) and magnetically soft in the outer shell. Those composites are used as exchange coupled composites for high-energy permanent magnet applications (Skomski et al., 2013). At the same time, it is possible to combine magnetic materials with different ordering, like ferro- and antiferromagnetic. In these systems represented by ferromagnetic Co core and antiferromagnetic CoO shell, it is possible to observe the effect of unidirectional shift of the magnetic hysteresis loop along the magnetic field axis, which is known as exchange bias (Nogués and Schuller, 1999). This effect is the key enabler of numerous spintronic devices, including magnetic read heads in hard disk drives and magnetic random access memory devices. To observe the exchange bias effect, the sample should be cooled through its Néel temperature in a magnetic field and the magnetic hysteresis is typically measured at temperatures $T < T_c$. The most pronounced is the shift of the magnetic hysteresis loop along the field axis. However, uncompensated moments can result also in a shift of the hysteresis loop along the moment axis. The vertical shift of the loop results from the field-invariant magnetization of the antiferromagnet, and the horizontal loop shift along the field axis is a trait of the ferromagnetic film. It is widely accepted that the horizontal loop shift is influenced by the field-invariant moment of the pinning antiferromagnet (Radu and Zabel, 2008) responsible for the vertical loop shift. This field-invariant uncompensated moment is induced by cooling under exchange coupling to the ferromagnet (Salazar-Alvarez et al., 2009). Typically, exchange bias is measured relying on superconducting quantum interference device (SQUID) or vibrating sample magnetometers (VSM). However, recent improvements in the magnetotransport characterization with a precise discrimination of the components of the resistance tensor (longitudinal vs. transversal resistances) allows to access horizontal and vertical loops shifts and provides further insights in the exchange bias effect (Kosub et al., 2015).

Hollow particles

In contrast to filled magnetic particles, magnetic responses of magnetic nanoshells (hollow particles or particles with a non-magnetic core) are strongly affected by the local geometrical curvatures of the shell. As discussed in Section “Curvilinear nanoarchitectures”, the presence of the geometrical curvature brings about two curvature-induced effects, namely, curvature-induced magnetic anisotropy and curvature-induced DMI. The latter interaction is chiral and allows to stabilize chiral magnetic textures including chiral domain wall and skyrmions even in an intrinsically achiral magnetic nanosized material. Those textures are in the heart of application concepts known as spin-orbitronics and antiferromagnetic spintronics. The aim here is to develop prospective energy efficient and ultra-high speed magnetic data storage devices, for instance relying on magnetic racetracks hosting magnetic solitons (domain walls and skyrmions). To synthesize metal and oxide hollow nanostructures, it is possible to explore template-assisted as well as template-free methods (He et al., 2012; An et al., 2008). The latter approaches are based on specific mechanisms, such as Ostwald ripening and Kirkendall effect. Synthesis strategies based on the Kirkendall effect are commonly used to synthesize spherical hollow nanoparticles of iron oxide (γ - Fe_2O_3 , Fe_3O_4) (Cabot et al., 2007; Khurshid et al., 2010), ferrimagnetic NiFe_2O_4 (Jaffari et al., 2010) and antiferromagnetic (CoO (Varón et al., 2013), NiO (Chu et al., 2019)) oxides, as well as ferromagnetic metals (Co (Simeonidis et al., 2011), FeCo (Tzitzios et al., 2011)). In addition to spherical hollow particles, nano-rings and nano-tubes can be prepared by properly changing the synthesis conditions (Roca et al., 2019).

Magnetoelectric and multiferroic particles

By coupling magnetic nanoparticles with other functional nanoscaled materials revealing different spontaneous order parameter like ferroelectric, it is possible to realize heterostructures which are known as artificial multiferroic materials (Spaldin and Ramesh, 2019). In this case, the resulting nanostructure will possess two different spontaneous order parameters like magnetization (order parameter of ferro- and ferrimagnetic materials) and electric polarization (order parameter of ferroelectric materials). These two order parameters can be coupled via mechanical strain relying on the effect of magnetostriction observed in magnetic materials and effect of electrostriction in ferroelectrics. For instance, by coupling ferrimagnetic CoFe_2O_4 core and ferroelectric BaTiO_3 shell (Kim et al., 2021), it is possible to realize multiferroic nanoparticle, which can be used for medical applications for deep brain stimulation (Kozielski et al., 2021). Alternatively, single phase multiferroic nanostructures like BiFeO_3 are explored as prospective data storage media, where the magnetic order parameter can be manipulated by means of electric fields, promising extremely efficient information media with an energy budget required for switching individual bit of information going potentially down to 1 aJ (Prasad et al., 2020).

Curvilinear shapes

There are numerous experimental methods, which allow fabricating complex 3D shaped magnetic nanoscale objects. Those include charged aerosol particles guided with electrostatic lens (Jung et al., 2021), glancing angular deposition (GLAD) (Mark et al., 2013; Phatak et al., 2014; Eslami et al., 2014), focused electron beam induced deposition (FEBID) (De Teresa et al., 2016; Fernández-Pacheco et al., 2017; Sanz-Hernández et al., 2017; Huth et al., 2018; Winkler et al., 2019; Plank et al., 2019; Phatak et al., 2020) or a combination of two-photon lithography and electrodeposition (Burmeister et al., 2012; Williams et al., 2018). By using these methods, it is possible to fabricate complex magnetic wireframe structures (Sahoo et al., 2018; Williams et al., 2018; Askey et al., 2020; Meng et al., 2021), magnetic nanohelices (Phatak et al., 2014; Sanz-Hernández et al., 2020; Phatak et al., 2020), magnetic Möbius rings at the nanoscale (Skoric et al., 2020), magnetic knots (Pip et al., 2020), magnetic DNA-like double helices (Sanz-Hernández et al., 2020) to name just a few appealing geometries. Furthermore, magnetic nanostructures can be formed by deposition of magnetic thin films and heterostructures on non-magnetic templates prepared either lithographically (optical or electron beam lithography), using self-assembly or combination of these two methods (Kappenberger et al., 2009). The templates of different dimensions (nm to μm range) and symmetries (e.g., cylindrical or spherical) can be fabricated relying on nanosphere lithography (Albrecht et al., 2005), nanoindentations (Schulze et al., 2010) and ion-induced patterning resulting in the formation of nanoripples, nanocones and nanopyramids (Korner et al., 2014).

2D magnetic materials

2D materials offer an interesting playground for magnetism community due to peculiar criticality behavior and possibility to realize well controlled heterostructures for spintronic applications (Gibertini et al., 2019). For instance, it is known that for 3D (nano) magnets a magnetic phase transition occurs at a finite temperature (Rigamonti and Carretta, 2015), see also Section “Critical phenomena”. At the same time, 1D systems can order only at $T = 0\text{ K}$ (Peierls, 1936). For 2D systems, the existence of magnetic long-range order at any finite temperature crucially depends on the number N_{sp} of relevant spin components, usually called spin dimensionality, and determined by the physical parameters of the system (for example, the presence and strength of magnetic anisotropy) (Gibertini et al., 2019). If the spin dimensionality $N_{\text{sp}} = 1$, the system has a strong uniaxial anisotropy and the spins point in either of the two possible orientations (“up” or “down”) along a given direction. The case of spin dimensionality $N_{\text{sp}} = 2$ corresponds to an easy-plane anisotropy that favors the spins to lie in a given plane, although the orientation within the plane is completely unconstrained. Isotropic systems are characterized with $N_{\text{sp}} = 3$ where there is no constraint on the direction of spins. For the latter case, the Mermin-Wagner-(Hohenberg) theorem states that thermal fluctuations destroy the long-range magnetic order in 2D systems at any finite temperature when the spin dimensionality is 3 (isotropic Heisenberg model) (Mermin and Wagner, 1966; Hohenberg, 1967). Hence, there is no isotropic 2D ferromagnet as long-wavelength excitations (spin waves) can be excited at any finite temperature as there is no gap in the spin wave spectrum (no anisotropy). 2D magnets with $N_{\text{sp}} = 2$ are described by the XY model. They do not possess a conventional transition to long-range order and the susceptibility diverges below a finite temperature. Berezinskii, Kosterlitz and Thouless pointed out that this divergence is associated with the onset of topological order, characterized by an algebraic decay of spin correlations and by the presence of bound pairs of vortex and antivortex arrangements of spins (Berezinsky, 1971; Berezinsky, 1972; Kosterlitz and Thouless, 1973). Below the Kosterlitz-Thouless temperature, T_{KT} , quasi-long-range magnetic order is established, and the existence of a finite order parameter is suppressed only marginally with the system size. Currently, there is active research with magnetic 2D materials, including the semiconducting layered van der Waals material CrI_3 (Huang et al., 2017) and a metallic 2D ferromagnet Fe_3GeTe_2 (Liu et al., 2017). For instance, $\text{Fe}_3\text{GeTe}_2/\text{hBN}/\text{Fe}_3\text{GeTe}_2$ heterostructures are integrated in 2D materials based magnetic tunnel junctions and reveal large tunneling magnetoresistance effect of more than 120% at 20 K (Wang et al., 2018). By realizing van der Waals $\text{CrI}_3/\text{WSe}_2$ heterostructures it becomes possible to control the spin and valley pseudospin in WSe_2 (Zhong et al., 2017). The change of the magnetization of the CrI_3 layer allows to change the photoluminescence intensity of WSe_2 relying on the ultrafast spin-dependent charge hopping across the heterostructure interface. The study of photoluminescence of valley pseudospin is suggested as a method to probe the dynamics of domains in 2D magnets.

Heterostructures of magnetic materials and topological insulators

Low-dimensional magnetic materials are also used to realize magnetic order in topological insulators (TIs) by proximity (Bhattacharyya et al., 2021). These heterostructures typically consist of a magnetic material and TI, e.g. $\text{Bi}_2\text{Te}_3/\text{Cr}_2\text{Ge}_2\text{Te}_6$. There are several mechanisms for magnetic proximity effect at the interface between a magnetic material and TI including the direct exchange interaction, magnetic extension, and surface-state-assisted exchange coupling (Bhattacharyya et al., 2021). The magnetic proximity effect has a relatively short length scale (few Å). Hence, the time-reversal symmetry is broken only at the interface of the TI and magnetic material, and not in the bulk of the TI. Therefore, TI is usually sandwiched between two magnetic layers, e.g. magnetic insulators with perpendicular magnetic anisotropy (Hou et al., 2019). Magnetic TI heterostructures like $(\text{Bi}_{0.25}\text{Sb}_{0.75})_2\text{Te}_3/\text{MnTe}$ and $\text{Bi}_2\text{Te}_3/\text{MnTe}$ are explored as spintronic devices (Chen et al., 2020).

Characterization of nanoscaled magnets

Magnetometry studies

To understand magnetic responses of individual magnetic nanostructures and their assemblies, it is important to know their switching field at target temperature, determine superparamagnetic transition temperature, Curie temperature, magnetization,

evaluate interactions between particles in an ensemble, etc. This is typically done by carrying out magnetometry measurements, for instance SQUID or VSM measurements. These devices allow to carry out magnetization vs. temperature measurements, measure magnetic hysteresis loops at different temperatures and in different geometry of the applied magnetic field. To determine relevant micromagnetic parameters, it is insightful to start with the temperature dependence of magnetization. In the vicinity of the Curie temperature, this dependence can be fitted to different criticality laws (e.g., Bloch 3/2 law for 3D materials) to get access to the exchange parameter. Furthermore, the superparamagnetic transition temperature, T_B , can be determined by performing zero field cooling (ZFC)—field cooling (FC) measurement of magnetic moment. To perform ZFC measurements, the sample is cooled down without applying magnetic field. Then it is exposed to a small magnetic field in the range of 10 Oe and the magnetic moment is measured as a function of temperature, starting at low temperatures. For the FC study, the procedure is similar, but the temperature changes from high to low temperatures in the presence of a small magnetic field. The blocking temperature can be estimated as the temperature corresponding to the maximum of the first derivative with respect to temperature of the difference between the ZFC and FC curves. This value is related to the magnetic volume, V , responsible for the magnetization reversal in magnetic nanoparticles with the anisotropy constant K_a . When the size of the particle is known, say from electron microscopy studies, the relaxation rate equation discussed in the section on superparamagnetism can be used to estimate the magnetic anisotropy constant. Alternatively, the blocking temperature can be measured by monitoring the temperature dependence of the coercive field. The temperature at which coercive field vanishes can be taken as a measure of T_B . For thin film samples or arrays of nanopatterned platelets with a well-defined easy axis of magnetization, it is possible to determine the anisotropy constant by measuring magnetic hysteresis loops along the easy and hard axis. The difference between the areas under the loops is the anisotropy energy. To assess coupling (magnetostatic vs. exchange) in the array of nanostructures, it is possible to apply the first-order-reversal-curves (FORC) analysis. FORC studies are especially useful for exchange coupled composites and exchange bias systems. For the latter, FORC analysis allows to access the switching field distribution and exchange bias (Fang et al., 2010). Furthermore, magnetometry can be used to evaluate the magnetic state of the sample (single domain, multidomain, superparamagnetic) by exploring the Day plots method (Dunlop, 2002).

Relying on the detection of magnetic stray fields, magnetic properties of individual nanostructures can be studied by the dynamic cantilever magnetometry (Degen et al., 2009; Weber et al., 2012; Mehlin et al., 2018; Braakman and Poggio, 2019), nano-SQUID magnetometry (Vasyukov et al., 2018), scanning Nitrogen vacancy (NV) magnetometry (Casola et al., 2018; Barry et al., 2020) and micro-Hall magnetometry that was applied for magnetic characterization of not only planar but also complex-shapes FEBID-fabricated nanostructures (Keller et al., 2018; Al Mamoori et al., 2018). Furthermore, the scanning reconfigurable magnetic force microscopy (MFM) (Kazakova et al., 2019; May et al., 2019; Corte-León et al., 2019) is applied to quantify 3D magnetization patterns of a magnetic nanoobject based on 2D data (Vock et al., 2014).

At the atomic scale, spin and orbital moments can be deduced by analyzing the sum rules in X-ray magnetic circular dichroism (XMCD) measurements (O'Brien and Tonner, 1994). Synchrotron-based methods can also access antiferromagnetic samples relying on the X-ray magnetic linear dichroism (XMLD). These contrast mechanisms provide the possibility to visualize magnetic states in nanostructures relying on full field and scanning X-ray microscopies like photoemission electron microscopy (PEEM) or scanning transmission X-ray microscopy (STXM). Due to their resolution down to about 10 nm, these techniques allow real space observation of magnetic states and magnetization reversal of individual nanostructures. Benefiting from the element specificity of XMCD and XMLD, it is possible to visualize magnetization processes peculiar to each layer in a heterostructure (say composed of Co and FeNi layers) or follow coupling between elements in the alloy (say FeTb alloy).

Magnetization dynamics studies

Magnetization dynamics is typically investigated using ferromagnetic resonance (FMR) methods, whose sensitivity for the study of magnetic nanoobjects could be substantially improved by utilizing microresonator loops (Lenz et al., 2019). FMR characterization can be also performed of nanostructures, which are exposed to a mechanical strain hence providing access to the magnetostrictive and magnetoelastic properties of nanoscaled objects (Challab et al., 2018; Challab et al., 2021). Linear dynamics (spin waves) can be studied relying on Brillouin light spectroscopy (BLS) (Demokritov et al., 2001), which can be also used in a highly-sensitive BLS microscopy mode (Schultheiss et al., 2019).

X-ray measurements are applied to study magnetization dynamics including real space visualization of spin waves in nanopatterned disks (Sluka et al., 2019) and motion of magnetic solitons in confined geometries (Büttner et al., 2015). For imaging of magnetic nanostructures and their dynamics, X-ray spectroholography (Eisebitt et al., 2004) is broadly applied also at free electron laser (FEL) facilities allowing to image magnetization dynamics in single shot experiments (Willems et al., 2017; Wang et al., 2012).

In addition to X-ray based imaging, magneto-optic Kerr effect (MOKE) magnetometry and microscopy is regularly applied to study magnetic hysteresis and visualize statics and dynamics of magnetic domain patterns in low-dimensional magnetic objects (McCord, 2015; Kuch et al., 2015). We note that dark-field MOKE magnetometry is applied for high-precision analysis of curvilinear structures (Sanz-Hernández et al., 2017).

Tomographic imaging of nanostructures

To visualize complex 3D geometries it is necessary to apply tomography-based approaches. Thus, XMCD-PEEM is used to image interior magnetization textures of curved magnetic nanoobjects relying on the transmission shadow contrast (Kimling et al., 2011). Furthermore, XMCD-PEEM and the magnetic transmission soft X-ray microscopy (MXTM) can be used in a tomography mode allowing to image the evolution of magnetic domain patterns of 3D mesoscale objects with a resolution in the range of 50 nm (Streubel et al., 2015a, 2015b). Even better resolution down to about 10 nm is offered by the hard X-ray magnetic tomography with

ptychographic scans (Donnelly et al., 2017). Electron-based methods including Lorentz transmission electron microscopy (TEM) (Phatak et al., 2011) and off-axis electron holography (Dunin-Borkowski, 1998; Midgley and Dunin-Borkowski, 2009) enable reconstruction of magnetic textures in planar (Kläui et al., 2005; Nord et al., 2019) and 3D curved (Biziére et al., 2013; Phatak et al., 2014; Phatak et al., 2020) nanoscale structures.

Spintronic and spinorbitronic characterization

To evaluate the spintronic properties of magnetic nanostructures, they are measured in a magnetoresistance or Hall-effect configuration. Typically, temperature and magnetic field dependent changes of the electrical resistance or impedance of the sample are evaluated. Magnetoresistance can be studied not only of planar but also of curved nanoscale objects including nanotubes (Rüffer et al., 2012; Zimmermann et al., 2018), magnetic spherical nanocaps (Kimling Née Moser et al., 2010), and ferromagnetic helices (Maurenbrecher et al., 2018). If the sample layer stack supports chiral effects, magnetotransport can be used to measure spin-orbit torques (SOTs) and get access to the DMI constant. The strength of SOTs can be assessed by measuring the effective magnetic field B_{SOT} , which introduces additional harmonic components to the measured Hall voltages (Meng et al., 2017; Volkov et al., 2021). To determine the effective field B_{SOT} of the anti-damping SOT, an external magnetic field is applied in-plane (B_{IP}) perpendicular to the current flow direction and the Hall resistance is recorded. The Hall resistance reveals the presence of the first and second harmonic signals, which allow to quantitatively determine the strength of B_{SOT} based on the following relation (Meng et al., 2017):

$$B_{\text{SOT}} = -2 \frac{\partial R_{\text{H}}^{2\omega} / \partial B_{\text{IP}}}{\partial^2 R_{\text{H}}^{\omega} / \partial B_{\text{IP}}^2}, \quad (15)$$

where R_{H}^{ω} and $R_{\text{H}}^{2\omega}$ are first and second harmonics of the Hall resistance. The obtained value of B_{SOT} is used to estimate the DMI constant accordingly to the equation (Kim et al., 2013):

$$D_0 = \frac{2A\gamma}{v_s} B_{\text{SOT}}, \quad (16)$$

where $v_s = Pjg\mu_B/(2eM_s)$ is the spin velocity, with P being the spin polarization of the current j , and e is the electron charge.

Conclusion

The chapter introduces the topic of magnetic nanostructures both theoretically and experimentally. We discuss basic theoretical concepts, which are needed to understand the ground and excited states of low dimensional samples. In this respect, not only single domain particles (and related superparamagnetism phenomenon) are introduced but also nanostructures supporting more complex textures as vortices, skyrmions, hopfions and domain walls are brought in focus. The equation of state as well as critical phenomena are introduced for ferro- and antiferromagnetic materials. Furthermore, we describe different fabrication strategies of magnetic nanoparticles ranging from chemical synthesis through preparation of nanostructures on non-magnetic templates to direct writing of complex 3D nanoarchitectures. Relevant characterization methods and techniques to study magnetization statics and dynamics of planar and 3D curved nanostructures are outlined. On the material science side, we cover not only homogeneous particles but also core-shell nanostructures. For the latter, we address ferro- and antiferromagnetic heterostructures and related phenomenon of exchange bias. Furthermore, we outline recent activities on artificial multiferroic heterostructures for low energy magnetic data storage and medical research for deep brain stimulation. Heterostructures of magnetic 2D materials and magnetic materials with topological insulators are discussed as well. Fabrication, characterization of these heterostructures and validation of their application potential is an appealing prospective research direction of nanoscale magnetism.

In addition to the discussed broad applications in magnetic data storage, biology, medicine, permanent magnets and printing technologies, magnetic nanostructures are explored for the research on artificial spin ice (Skjærvø et al., 2019). Artificial spin ice is a system with a degenerate ground state represented by arrays of nanopatterned macrospins (Ising-type nanomagnets) interacting via dipolar magnetic coupling. There are proposals and first experimental reports to use artificial spin ice for the realization of artificial spin glasses (Saccone et al., 2019; Saccone et al., 2022). These activities are appealing for future research as they offer a convenient material science platform to validate theoretical ideas for understanding of the functionality of human brain and realization of artificial neuronal networks for prospective energy efficient computing systems. Taking into account the current advances in the fabrication of 3D magnetic wireframe structures (Keller and Huth, 2018; May et al., 2019), which could act as 3D artificial spin ice systems, it is insightful to attempt the realization of 3D artificial spin glasses. For these studies, not only design and realization of an appropriately disordered 3D array of nanomagnets represent the experimental challenges but also advanced characterization methods, relying on electron-based and X-ray-based tomography and holography techniques (Wolf et al., 2021; Donnelly et al., 2015) would need to be applied.

Beside filled nanoparticles and planar nanoscale objects, we discuss geometrically curved shells (hollow particles). The theoretical approach of curvilinear magnetism is introduced to guide the analysis of complex responses of geometrically curved magnetic shells. Due to the possibility to tailor magnetic responses (chiral and anisotropic) relying on geometrical curvature, curvilinear nanoscaled objects attract strong attention both from the fundamentally and application oriented research communities. In this respect, integration of curved magnetic nanostructures in spintronic and spinorbitronic devices should be addressed in future

research to confirm experimentally the appealing theoretical predictions of artificial magnetoelectric materials (Volkov et al., 2019) and high-speed racetracks based on tubular architectures (Yan et al., 2010). Until recently, the primary focus in 3D and curvilinear magnetism research lay on the impact of the geometrical curvature on magnetization textures in curved nanowires and thin films (Makarov et al., 2022). Going beyond the study of micromagnetic textures, it is insightful to address topological magnetic field nanotextures specific to 3D curved geometries (Donnelly et al., 2021). In contrast to topological magnetization textures like domain walls and skyrmions whose relevance for spintronic and spinorbitronic devices is well established, the full potential of topological magnetic field nanotextures for research and applications is yet to be understood and explored for spintronics, 3D magnonics (Barman et al., 2021) and related concepts of reservoir computing (Grollier et al., 2020). The research on 3D and curvilinear magnetism in general and topological magnetic field nanotextures in particular stimulates further development of fabrication methods to produce high quality, complex shaped magnetic objects with tunable magnetic interactions including FEBID, chemical synthesis, strain engineering origami, two photon laser lithography, or templated self-assembly.

Abstract

In metallic systems with spin-orbit coupling a longitudinal charge current may generate a transverse pure spin current; *vice-versa* an injected pure spin current may result in a transverse charge current. Such direct and inverse spin Hall effects share the same microscopic origin: intrinsic band/device structure properties, external factors such as impurities, or a combination of both. They allow all-electrical manipulation of the electronic spin degrees of freedom, i.e., without magnetic elements, and their transverse nature makes them potentially dissipationless. It is customary to talk of spin Hall effects in plural form, referring to a group of related phenomena typical of spin-orbit coupled systems of lowered symmetry.

Key points

- History and definition of the effect(s)
- Phenomenology and concepts: spin-orbit coupling in solids, charge *vs.* spin currents, bulk *vs.* edge effects
- Experiments: from low- to room temperature, diversity and complexity of setups
- Theory: the challenge of complexity, competition between different microscopic mechanisms, Onsager reciprocity
- The broader context: generalizations of the spin Hall effect(s) and suggested further readings

Introduction

A charge-carrying state in a metallic system is a (non-equilibrium) momentum-ordered state of an electronic ensemble: a collection of quasielectrons¹ moving preferentially in a given direction, see Fig. 1(a). However quasielectrons carry around their internal spin degrees of freedom, too. For their ensemble to be spin carrying some form of spin order is needed. There are two basic scenarios:

- Spin order is independent of momentum order. This is the situation in a ferromagnet, where the spins of charge carriers align with the magnetization via exchange coupling independently of their orbital motion.
- Spin and momentum orders are correlated. This is possible in the presence of spin-orbit coupling, which quite generally creates correlations between orbital motion (momentum) and spin.

Consider the second scenario, and to be definite the somewhat special situation sketched in Fig. 1(b), where quasiparticles with opposite spin projection along z move in opposite directions. An ensemble of such particles does not carry any overall charge—the associated charge current is zero, $j^c = 0$ —but it does carry angular momentum: it is a pure spin-carrying state sustaining a “pure spin current” $j^s \neq 0$

$$j^c \equiv q(j^{\uparrow} + j^{\downarrow}) = 0 \quad (1)$$

¹I will restrict my discussion to systems where well-defined fermionic quasiparticles exist and make up a Fermi liquid. Words such as “quasielectron” and “electron” or “quasiparticle” and “particle” will be used interchangeably.

Fig. 1 Left panel: A charge current $\mathbf{j}^c$ along x , i.e., an overall spin-unpolarized ensemble of quasielectrons moving in the y direction. Right panel: A z -polarized pure spin current $\mathbf{j}^s$ flowing along x .

Fig. 2 Left panel: spin Hall effect. An x -flowing charge current is injected, and a z -polarized pure spin current along y is generated via spin-orbit coupling. Right panel: inverse spin Hall effect, where the role of the spin and charge currents are exchanged. Note that in the sHe/isHe the charge current, spin current and the spin quantization axis are all orthogonal to each other.

$$\mathbf{j}^s \equiv \frac{\hbar}{2} (\mathbf{j}^\uparrow - \mathbf{j}^\downarrow) \neq 0, \quad (2)$$

with q the quasiparticle charge and $\hbar$ the reduced Planck constant.

In the presence of spin-orbit coupling a transverse $\mathbf{j}^s$ can be generated from a longitudinal $\mathbf{j}^c$, or *vice-versa*, see Fig. 2. These are respectively the spin Hall effect (sHe) (Dyakonov and Perel, 1971; Hirsch, 1999) and its reciprocal version, the inverse spin Hall effect (isHe) (Dyakonov and Khaetskii, 2006; Engel et al., 2007). The sHe was first predicted by Dyakonov and Perel in 1971 (Dyakonov and Perel, 1971) but got his current name only in 1999, when Hirsch (Hirsch, 1999) sort of re-discovered it and its fortune really started. The isHe followed a similar path. In the geometry from Fig. 2 one has

$$j_y^s = (\hbar/q)\theta^{\text{sHe}} j_x^c, \quad (3)$$

$$j_x^c = (q/\hbar)\theta^{\text{isHe}} j_y^s \quad (4)$$

with θ^{sHe} , θ^{isHe} the spin Hall and inverse spin Hall angles. Note that from now on upper (lower) indices will denote charge/spin (real space) components. The spin Hall/inverse spin Hall angles are crucial quantities used as standard measure for the spin-charge conversion efficiency of a given setup (Valenzuela and Tinkham, 2006; Hahn et al., 2013a; Obstbaum et al., 2014; Sinova et al., 2015). In Sections “Phenomenology and basic concepts” and “Theory” we will show that their existence can be expected based on crude but general arguments, while their precise origin and values are extremely sensitive to the microscopic details of the system.

The sHe and isHe exist also in quantized form. Indeed, the “quantum spin Hall insulator” is the paradigmatic example of a time-reversal symmetric two-dimensional topologically insulating phase (Hasan and Kane, 2010). The latter is a phase of matter which is insulating in the bulk but hosts two perfectly conducting edge states which are time-reversed partners—up electrons moving in one direction, down in the opposite. In simple terms, a quantum spin Hall phase can be thought of as two time-reversed copies of a (time-reversal broken) quantum Hall state. Its existence was confirmed experimentally in HgCdTe quantum wells in 2007 (König et al., 2007). I will not discuss it further here, but refer the interested reader to the Encyclopedia Chapter “Topological Effects.”

The sHe and isHe are nowadays routinely employed in metallic systems to inject and/or read out spin signals via electrical means, and their technological relevance is rapidly on the rise since the early 2000s (Dyakonov and Khaetskii, 2006; Engel et al., 2007; Sinova et al., 2015; Fert and Dau, 2019). The rest of the Chapter will focus uniquely on them. In particular I will not discuss the anomalous Hall effects, closely related phenomena which require however to break time-reversal symmetry (Dyakonov and Khaetskii, 2006; Nagaosa et al., 2010). The reader should indeed keep in mind that the spin Hall effect I will deal with in this Chapter actually belongs to a larger class of phenomena which may appear whenever quasiparticles with internal structure move in a non-trivial medium, i.e., not just in the vacuum.²

²In condensed matter one customarily talks of “pseudospin” internal degrees freedom, such as sublattice or valley pseudospin in graphene, which may give rise to different forms of “pseudospin Hall effect.”

Phenomenology and basic concepts

The role of spin-orbit coupling

Take an electron moving with velocity $\mathbf{v}$ in presence of an electric field $\mathbf{E}$. In its reference frame the electron sees a velocity-dependent magnetic field

$$\mathbf{B}'(\mathbf{v}) = -\gamma \frac{\mathbf{v}}{c} \times \mathbf{E}, \quad \gamma = \frac{1}{\sqrt{1 - v^2/c^2}} \quad (5)$$

which couples to its spin $\mathbf{s} = (\hbar/2)\boldsymbol{\sigma}$, with $\boldsymbol{\sigma}$ the vector of Pauli matrices, as usual

$$H_{\text{so}} \sim \mathbf{s} \cdot \mathbf{B}' \sim \mathbf{s} \cdot (\mathbf{v} \times \mathbf{E}). \quad (6)$$

Here c is the speed of light. This is a primitive derivation of the spin-orbit interaction.

Let us assume that $\mathbf{E} = -\nabla V_{\text{ext}}$ comes from an external source, e.g., the (random) electrostatic potential from an impurity, see Fig. 3(a). The quasiparticle spin thus couples to a non-homogeneous field $\mathbf{B}'(\mathbf{v}) \rightarrow \mathbf{B}'(\mathbf{v}, \mathbf{r})$, similarly to what happens in a Stern-Gerlach apparatus. This has various consequences, e.g., it causes spin-flip (Elliot-Yafet) relaxation, but in particular it results in a spin-dependent force $\mathbf{F} \sim -\nabla [\mathbf{s} \cdot \mathbf{B}']$ orthogonal to $\mathbf{v}$

$$\mathbf{F}_{\perp}^{\uparrow} = -\mathbf{F}_{\perp}^{\downarrow} \sim -\nabla_{\perp} B'. \quad (7)$$

This sideways separation of spin-up and spin-down quasi-particles is referred to as Mott skew scattering, and can split an incoming flux of unpolarized electrons into a transverse pure spin current, i.e., it yields a finite θ^{stie} . It is an “extrinsic” mechanism requiring the presence of scattering centers (Hirsch, 1999; Dyakonov and Khaetskii, 2006; Engel et al., 2007; Culcer et al., 2010), but a finite θ^{stie} may also have origins which are “intrinsic” to the device and/or band structure. Consider for example $\mathbf{E} = -\nabla V_{\text{int}}(z)$, with $V_{\text{int}}(z)$ an internal potential which defines your structure, see Fig. 3 (b). Such a potential breaks z inversion symmetry and constrains electrons to move in the x - y plane, as in semiconductor quantum wells. One has

$$H_{\text{so}} \sim \mathbf{s} \cdot \mathbf{v} \times \mathbf{e}_z. \quad (8)$$

Now $\mathbf{s}$ couples to a homogeneous $\mathbf{B}'(\mathbf{v})$ which always points in plane, called a Rashba field (Bychkov and Rashba, 1984; Winkler, 2003). The eigenstates of the problem are spinors whose quantization axis depends on their direction of motion. As sketched in Fig. 3(b), under an electrical bias one expects spin-momentum correlations to arise leading to a transverse, out-of-plane-polarized spin current—that is, to a non-vanishing θ^{stie} . Recall that in this intrinsic example inversion symmetry was explicitly broken. Some form of spatial symmetry-breaking is indeed a requirement of intrinsic scenarios beyond the present Rashba case (Engel et al., 2007; Winkler, 2003). On the other hand time-reversal symmetry is preserved by spin-orbit interaction.

Besides the canonical intrinsic and extrinsic mechanisms just described, other sources for the spin Hall effects include dynamical couplings with phonons (Gorini et al., 2015; Karnad et al., 2018) or spin fluctuations (Okamoto et al., 2019), the interplay of impurity and magnon scattering (Ohnuma et al., 2016), or fluctuations of the Rashba field (Dugaev et al., 2010). Irrespectively of the origin, and just as a normal Hall current, the spin Hall current is transverse with respect to the drift velocity and thus potentially dissipationless.

Size and form of (effective) spin-orbit coupling

Since charge carriers in a metallic system move at the Fermi velocity $v_F \ll c$, should one expect H_{so} to be only a negligible relativistic correction? The answer is “not necessarily.” Electrons in solids do not move in the vacuum, but constantly get close to ionic cores from the lattice where unscreened very strong electric fields exist, compensating for their (relativistically) slow velocity. One can indeed show that s -wave Bloch electrons close to the Fermi energy feel an effective spin-orbit interaction which reads

Fig. 3 Left panel: Electrons with opposite spins are deflected differently by a scattering potential $V_{\text{ext}}(\mathbf{r})$. The dashed black line is the trajectory without spin-orbit corrections. Right panel: Electrons confined to two dimensions by $V_{\text{int}}(z)$. The internal velocity-dependent field, see Eq. (8), defines the spin quantization axis, shown with dotted lines. The two electrons are time-reversed partners, and when driven by an electric field along x their spins will precess around the new (tilted) quantization axis, yielding out-of-plane components $\pm s_z$ shown in blue. The result is a z -polarized spin current in the transverse y direction.

$$H_{\text{so}} = \lambda \boldsymbol{\sigma} \times \nabla \delta V \cdot \mathbf{p}, \quad (9)$$

with δV any potential other than that of the host lattice, e.g., $\delta V = V_{\text{ext}}$ or $\delta V = V_{\text{int}}(z)$ from our previous examples. While the form of H_{so} is the same as in the vacuum, the coupling constant λ is an effective Compton wavelength strongly renormalized by the lattice: $\lambda/\lambda_0 \sim 10^6$, with λ_0 the vacuum Compton wavelength. The standard machinery behind such renormalization is $\mathbf{k} \cdot \mathbf{p}$ theory, which, together with some auxiliary techniques (Löwding partitioning, Schrieffer-Wolff transformation, ...), is just a systematic way of building low-energy models starting from the band structure (Bloch states) of a given lattice—at the simplest level it leads, e.g., to the effective mass description of electrons in solids (Engel et al., 2007; Winkler, 2003). Eq. (9) can actually be generalized to

$$H_{\text{so}} = \mathbf{b}(\mathbf{p}) \cdot \boldsymbol{\sigma}, \quad (10)$$

which looks like Zeeman/exchange coupling with a momentum-dependent internal field $\mathbf{b}(\mathbf{p})$. The latter defines a momentum space spin texture—its vectorial image in reciprocal space—of central importance well beyond spin Hall physics.³ This form of effective spin-orbit interaction is valid beyond the two example scenarios previously introduced, and is the starting point for most discussions of spin-orbit coupled transport phenomena (Engel et al., 2007; Winkler, 2003).⁴

A closer look at spin currents

The spin Hall/inverse spin Hall angles, see Eqs. (3) and (4), are crucial quantities in spin Hall physics. However to define them one needs to know exactly what a spin current is, which is not a completely trivial task. Let us see why.

Charge is a conserved quantity respecting the continuity equation

$$\partial_t n + \nabla \cdot \mathbf{j}^c = 0, \quad (11)$$

with n the charge (particle) density and $\mathbf{j}^c = \mathbf{v}n$ the current. In formal terms, this is a consequence of gauge invariance: charge (particle number) is the conserved quantity associated with the $U(1)$ gauge symmetry of the system—a case of Noether's theorem.

A purely orbital Hamiltonian H_0 without spin-orbit interaction cannot affect the dynamics of the spin degrees of freedom: not only charge, but also spin is conserved for H_0 . Formally H_0 is spin-rotation invariant, which for spin 1/2 particles means that it has $SU(2)$ gauge symmetry. Spin conservation yields the continuity equation

$$\partial_t s^a + \nabla \cdot \mathbf{j}^a = 0, \quad a = x, y, z, \quad (12)$$

with s^a the density of a -polarized electrons, and $\mathbf{j}^a = \mathbf{v}s^a$ the corresponding a -spin current density.

In the presence of spin-orbit coupling, $H_0 \rightarrow H = H_0 + H_{\text{so}}$, spin rotation symmetry is broken and spin is not conserved anymore. Consider first extrinsic spin-orbit due to diluted impurities. In this case spin is not conserved during scattering events, but remains so between them. The definition $\mathbf{j}^a = \mathbf{v}s^a$ is thus good during flight, but at each scattering the a -polarized flux may rotate, partially split and lose weight due to spin-flip scattering. The result is a spin relaxation rate $1/\tau_s^a$, with τ_s^a the a -spin lifetime, and some further extrinsic spin torque Γ_{ext}^a

$$\partial_t s^a + \nabla \cdot \mathbf{j}^a = -\frac{s^a}{\tau_s^a} + \Gamma_{\text{ext}}^a. \quad (13)$$

The extra torque describes spin non-conservation effects beyond simple relaxation, e.g., skew-scattering physics, which may directly couple spin and charge degrees of freedom.

If intrinsic spin-orbit coupling is present things are more complicated. First, in this case the velocity $\mathbf{v} = \partial_{\mathbf{p}} H$ does not in general commute with the spin operator, which is obvious looking at Eq. (10). One can still generalize the spin current definition by symmetrization

$$\mathbf{j}^a = \frac{1}{2} \{\mathbf{v}, s^a\}, \quad (14)$$

with $\{A, B\} = AB + BA$ the anticommutator. However spin is now intrinsically—i.e., everywhere and always—not conserved, ergo the continuity equation obeyed by such a current must be modified by an intrinsic spin torque Γ_{int}^a

$$\partial_t s^a + \nabla \cdot \mathbf{j}^a = \Gamma_{\text{int}}^a. \quad (15)$$

The precise form of the torque is fixed by the internal spin-orbit field (10). The intrinsic lack of a conservation law means that $\mathbf{j}^a$, and thus Γ^a are not uniquely defined now. This is no fundamental problem, in the sense that not all physically meaningful currents need be conserved. It can however be a delicate operative problem, as changing the definition of $\mathbf{j}^a$ will change the definitions of the spin Hall/inverse spin Hall angles, which is what experiments typically aim at measuring. Similarly, it will modify the estimates for the spin accumulations generated by the current, the accumulation being another popular observable. Indeed, it is not always obvious

³In the presence of $\mathbf{b}(\mathbf{p})$ the Hilbert space of the problem is usually equipped with a non-vanishing Berry curvature, with the potential for hosting non-trivial topological phases.

⁴There are situations in which an internal field $\mathbf{b}(\mathbf{p})$ appears for microscopic reasons which have nothing to do with relativistic spin-orbit interaction. The field thus couples to some internal pseudospin degree of freedom $\boldsymbol{\tau}$ of the low-energy quasiparticles, $\mathbf{b}(\mathbf{p}) \cdot \boldsymbol{\tau}$. See comments in the closing of Section “Introduction”.

how (if) local spin currents somewhere, say in the bulk, are connected with local spin accumulations elsewhere, e.g., at the sample's edges (Dyakonov and Khaetskii, 2006; Sonin, 2007a, 2010a; Adagideli et al., 2007; Gorini et al., 2012). These issues are recurrently discussed in the specialized literature (Sonin, 2007a, 2010a,b; Adagideli et al., 2007; Gorini et al., 2012; Rashba, 2003; Nikolić et al., 2006; Shi et al., 2006; Sugimoto et al., 2006; Tokatly, 2008; Khaetskii, 2014) and can be dealt with in different ways, for example:

- One can avoid referring to spin currents within the spin-orbit coupled region, and define them only in the metallic electrodes attached to sample, where H_{so} is negligible. This is the picture naturally arising in the Landauer-Büttiker approach to transport (Jacquod et al., 2012). It is often more or less implicitly assumed in phenomenological discussions of experiments.
- One can focus on spin accumulations, i.e., consider the equation of motion for the spin density without assuming a given form for the spin currents. The appropriate form of the currents may be derived from the density equations, notably in the diffusive regime (Adagideli et al., 2007; Burkov et al., 2004; Mal'shukov et al., 2005; Raimondi et al., 2006).
- One can use the non-Abelian gauge properties of the Hamiltonian H , i.e., its spin rotation $[SU(2)]$ properties, to define spin currents much as color currents are defined in high-energy physics (Tokatly, 2008; Gorini et al., 2010). This approach removes any ambiguity from the definition of $\mathbf{j}^a$, Γ^a , but cannot directly be exploited for any form of $\mathbf{b}(\mathbf{p})$. I will comment further on it in Section "Theory."
- One can try to define a conserved spin current by combining $\mathbf{j}^a$ and Γ^a (Shi et al., 2006; Sugimoto et al., 2006).

There is arguably no single "best" approach. One should decide which way to go based on the specific physical situation, and—if the physics allow—on personal tastes. It should also be kept in mind that both extrinsic and intrinsic processes are present in typical setups, and that they may yield further intrinsic-extrinsic crossed processes, i.e., the corresponding torques are not simply additive (Raimondi and Schwab, 2009; Raimondi et al., 2012). Moreover—and independently of the spin current definition—continuity equations like (12), (13), or (15) must be supplemented with appropriate boundary conditions, e.g., at interfaces between different materials or at the edges of the system, which may yield additional (local) torques (Adagideli et al., 2007; Khaetskii, 2014; Raimondi et al., 2006; Adagideli and Bauer, 2005; Tserkovnyak et al., 2007; Mal'shukov et al., 2007; Amin and Stiles, 2016; Tölle et al., 2018).

Experiments

The first spin Hall experiments were performed in the 1970s and 1980s in semiconductors (Dyakonov and Khaetskii, 2006), but relatively few got interested at the time. The business became fashionable in the early 2000s, and the spin Hall effects are nowadays not only the object of fundamental research (Zhu et al., 2019; Nakagawara et al., 2019; Li et al., 2021; Yanez et al., 2021; Boverter et al., 2021), but also established tools in more application-oriented settings (Fert and Dau, 2019; Liu et al., 2012; Safeer et al., 2020; Karube et al., 2020). In fact, while the first experiments were performed at fairly low temperatures (a few to a few tens of Kelvins) room temperature measurements are routine today, and large spin Hall angles have been reported in different materials. To give a rough idea of the progression, the spin Hall angle reported in a pioneering experiment by Valenzuela and Tinkham in 2006 was $\theta^{\text{sHe}} \sim 10^{-4}$ in Al at $T = 4.2$ K, while less than 10 years later room temperature measurements in Pt, Ta or W reached $\theta^{\text{sHe}} \sim 10^{-1}$ (Hahn et al., 2013a; Obstbaum et al., 2014; Liu et al., 2012; Rojas-Sánchez et al., 2014; Pai et al., 2012).

The numerous experimental schemes available can roughly be divided into three classes.

- Optical setups, historically the first to be used to detect the sHe/isHe, exploit the interaction between polarized light and the spin of charge carriers. For example, circularly polarized light can be used to generate local non-equilibrium spin accumulations which later diffuse through the system. The diffusion spin current can then be converted by the isHe into charge signals measured with standard electrodes, see Fig. 4(a). On the other hand, spin accumulations can be measured by circularly polarized

Fig. 4 Left panel: A broad spot of circularly polarized light creates a non-equilibrium spin polarization $\delta s'$ at a sample's surface (shaded region), and a diffusion spin current $j_z^y \sim \partial_z \delta s'$ flows into the 3D bulk. Here the isHe generates a transverse charge current j_x yielding a finite output voltage V_{isHe} . Setups of this kind were proposed already in the early days of spin Hall physics (Dyakonov and Khaetskii, 2006). Right panel: In a 2D system the charge current j_x from an applied bias V is converted into a spin Hall current j_y^z . The resulting spin accumulation at the edges (shaded region) is measured by Kerr rotation of scattered light (red). The technique was employed in the first experimental observation of the sHe in a 2D electron gas (Kato et al., 2004), and a similar one in a 2D hole gas (Wunderlich et al., 2005). The connection between bulk spin currents and edge spin accumulations can however be less direct than this cartoon suggests (Dyakonov and Khaetskii, 2006; Adagideli et al., 2007; Sonin, 2010a; Gorini et al., 2012; Nikolić et al., 2006).

electroluminescence or magneto-optical Kerr and Faraday effects. An example is shown in Fig. 4(b), where the spin accumulation at the edge of the system generated by the sHe is measured by the degree of (Kerr) rotation of light scattered off the sample. All-optical schemes are also employed (Werake et al., 2011; Seifert et al., 2016), allowing in particular time-resolved experiments on ultra-short (THz) timescales (Werake et al., 2011)—which are not accessible to electronic systems.

- Magneto-electric (spin pumping, spin torque) setups, relying on the interplay between magnetization and spin dynamics (Tserkovnyak et al., 2005). Fig. 5 shows a paradigmatic example: a spin current $\mathbf{j}_{\text{in}}^s$ is injected from an out-of-equilibrium magnetic element, e.g., a (conducting or insulating) magnet driven by microwaves, and converted into a charge current $\mathbf{j}_{\text{out}}^c$ collected at a normal metallic electrode. The latter can actually be used to run the experiment under “reverse bias”: $\mathbf{j}_{\text{in}}^c$ is injected, and one measures the torque that the resulting $\mathbf{j}_{\text{out}}^s$ exerts on the adjacent magnet. The presence of magnetic elements considerably increases the degree of complexity of the overall system, and may lead to additional effects which are however beyond the scope of this short overview (Tserkovnyak et al., 2005; Manchon et al., 2019). Time-dependent experiments are also performed, e.g., to measure AC spin Hall effects (Hahn et al., 2013b; Wei et al., 2014; Weiler et al., 2014).
- All-electrical setups, conceptually probably the simplest. Fig. 6(a) shows a most basic one, without any magnetic element: A charge current $\mathbf{j}_{\text{in}}^c$ is injected by a metallic electrode, is converted into a spin signal by the sHe, and finally re-converted by the isHe into an outgoing $\mathbf{j}_{\text{out}}^c$ collected at some other electrode. A very popular scheme requiring a magnetic electrode is instead sketched in Fig. 6(b). Both are non-local—input electrodes are somewhere, output electrodes elsewhere—a common feature in spin Hall setups (Valenzuela and Tinkham, 2006; Takahashi and Maekawa, 2007).

The boundary between classes is clearly blurred, and mixed techniques are often employed. An important general observation is that experimental setups—apart perhaps from the simplest all-electrical ones—are fairly complex, consisting of multiple elements of different nature subject to various kinds of drivings. Paired with the vast number of spin-charge (or charge-spin) conversion channels available in any given system, this makes for interesting debates concerning possible microscopic interpretations of experiments.⁵

Fig. 5 Left panel: Sketch of a spin pumping setup. Microwaves in a ferro-/ferrimagnet FM at frequency ω drive the magnetization, $\mathbf{M} = M\mathbf{n} \rightarrow \dot{\mathbf{M}}(\dot{\mathbf{n}}) = M\dot{\mathbf{n}}(\dot{\mathbf{n}})$. Its precession injects angular momentum into the underlying spin-orbit coupled normal metal, generating a spin current $\mathbf{j}^s$. The latter is converted by the isHe into a charge current $\mathbf{j}^c$ and *ergo* a measurable voltage V_{isHe} , in general with both DC and AC components (Wei et al., 2014; Weiler et al., 2014; Jiao and Bauer, 2013). Right panel: A reverse-bias scenario, in which a charge current at frequency ω is injected and converted by the sHe into an AC spin current. The latter exerts a torque on $\mathbf{M}$ and drives its precession. There are numerous DC and AC variations to these schemes, involving many different magneto-resistive effects modulated by spin-orbit interaction, see Sinova et al. (2015), Fert and Dau (2019) for an overview.

Fig. 6 Left panel: Hall bar geometry without magnetic elements. The injected charge current $\mathbf{j}_{\text{in}}^c$ is converted into a transverse spin current $\mathbf{j}_s$ by the sHe. The latter is converted back into a charge current $\mathbf{j}_{\text{out}}^c$ by the isHe in the right arm of the setup, yielding a finite V_{isHe} . One of the earliest implementations of this setup was used to measure the ballistic sHe in a HgTe quantum well (Brüne et al., 2010). Right panel: non-local setup with a ferromagnetic (FM) electrode, shown in dark gray, deposited on top of a T-shaped metallic film. The injected current $\mathbf{j}_{\text{in}}^c$ is drained to the left contact, since the right metallic arm is at the same electrochemical potential as the FM electrode. The current $\mathbf{j}_{\text{in}}^c$ is spin polarized, therefore it creates a non-equilibrium spin accumulation underneath the FM contact, shown by the shaded area. Part of it diffuses toward the right, yielding a pure spin current $\mathbf{j}_s$ which is then converted by the isHe into a measurable transverse voltage V_{isHe} . The scheme was first employed by Valenzuela and Tinkham (2006).

⁵The spin galvanic and inverse spin galvanic effects are very often crucial “partners” of the spin Hall effects (Ganichev et al., 2002; Ganichev et al., 2019; Shen et al., 2014; Gorini et al., 2017). They are another common channel of spin-charge/charge-spin conversion, discussed in detail in a dedicated Encyclopedia Chapter.

Theory

An instructive example and the general framework

The spin Hall effects are non-equilibrium phenomena handled with the usual arsenal of transport theory techniques: Keldysh formalism, density matrix and semi-classical kinetics, Kubo formula, Landauer-Büttiker formalism. . . . Irrespective of the techniques employed, a source of substantial theoretical challenges is complexity. In crude terms, the Hamiltonian of a spin Hall system requires numerous ingredients, recall the discussion from Section “Experiments.” The resulting quasiparticle dynamics are in general quite sensitive to the presence/absence of, and competition between, each.

To see this in a concrete way it is instructive to start from the barebone model of an ideal Rashba system

$$H_R = \frac{p^2}{2m} + \frac{\alpha}{\hbar} [p_y \sigma^x - p_x \sigma^y], \quad (16)$$

where m is the effective electron mass and $\alpha \sim \nabla V_{\text{int}}(z)$ the Rashba coupling constant, proportional to the (effective) electric field confining the electrons to the x - y plane—see the heuristic discussion in Section “Phenomenology and basic concepts,” Eq. (8).

Given H_R , the goal is to compute the frequency-dependent spin Hall conductivity $\sigma^{\text{sHe}}(\omega)$, defined as

$$j_y^z(\omega) = \sigma^{\text{sHe}}(\omega) E_x(\omega), \quad (17)$$

with j_y^z the z -polarized spin current in the y direction. The standard choice is to take the symmetrized spin current definition (14)—other choices are possible, recall the discussion from Section “Phenomenology and basic concepts,” and the consequences will be addressed below. The spin Hall conductivity can be written in terms of the spin current-charge current Kubo response function $\langle\langle j_y^z; j_x \rangle\rangle_\omega \equiv -\frac{i}{\hbar} \int_0^t [j_y^z(t), j_x(0)] e^{i\omega t} dt$, with $[A, B] = AB - BA$ the commutator (Landau et al., 2008). Since the charge current couples to the vector potential as $\mathbf{j} \cdot \mathbf{A}$, and $E_x(\omega) = -i\omega A_x(\omega)$, one has

$$\sigma^{\text{sHe}}(\omega) = \frac{\langle\langle j_y^z; j_x \rangle\rangle_\omega}{i\omega}. \quad (18)$$

Once the DC $\sigma^{\text{sHe}} \equiv \lim_{\omega \rightarrow 0} \sigma^{\text{sHe}}(\omega)$ is known the spin Hall angle follows

$$\theta^{\text{sHe}} = \frac{q}{\hbar} \frac{\sigma^{\text{sHe}}}{\sigma_x^c}, \quad (19)$$

with σ_x^c the longitudinal DC charge conductivity. An explicit computation yields the “universal” DC result

$$\sigma_{\text{clean}}^{\text{sHe}} = \frac{e}{8\pi\hbar}, \quad (20)$$

with the electron charge $q = -e < 0$. The subscript “clean” highlights that the system is without any defects. Such a beautiful result, due to the intrinsic Berry phase of electrons on the Rashba Fermi surface, is unfortunately very fragile. If one adds dirt to the model, i.e., a random impurity potential, $H_R \rightarrow H_R + V_{\text{imp}}(\mathbf{r})$, the spin Hall conductivity exactly vanishes

$$\sigma_{\text{dirty}}^{\text{sHe}} = 0. \quad (21)$$

The vanishing is diagrammatically subtle: since it comes from vertex corrections, it cannot be guessed by simply introducing a disorder broadening of the momentum eigenstates in the Kubo response kernel (Schwab and Raimondi, 2002; Inoue et al., 2004; Raimondi and Schwab, 2005). Indeed, it was overlooked at first in the scientific literature (Sinova et al., 2004). On the other hand, it is easily understood with kinetic arguments (Dimitrova, 2005; Chalaev and Loss, 2005), since the homogeneous continuity equation for the y -spin component reads

$$\partial_t s^y = - \underbrace{\frac{2m\alpha}{\hbar^2} j_y^z}_{\Gamma_{\text{int}}^y}. \quad (22)$$

At steady state the spin current $j_y^z = 0$.

Eq. (21) is as fragile as its clean counterpart (20). If one further adds extrinsic spin-orbit interaction, that is spin-orbit interaction with the impurity potential, $H_R \rightarrow H_R + V_{\text{imp}}(\mathbf{r}) + \lambda \boldsymbol{\sigma} \times \nabla V_{\text{imp}}(\mathbf{r}) \cdot \mathbf{p}$, the spin Hall conductivity is non-zero

$$\sigma_{\text{int+ext}}^{\text{sHe}} \neq 0, \quad (23)$$

and furthermore depends non-trivially on different system parameters. In particular (Raimondi and Schwab, 2009; Raimondi et al., 2012)

$$\sigma_{\text{int+ext}}^{\text{sHe}} \neq \sigma_{\text{int}}^{\text{sHe}} + \sigma_{\text{ext}}^{\text{sHe}}. \quad (24)$$

Equivalent results would have been reached starting from the (linear) Dresselhaus model

$$H_D = \frac{p^2}{2m} + \frac{\beta}{\hbar} [p_x \sigma^x - p_y \sigma^y], \quad (25)$$

where the coupling constant β is now due to bulk inversion asymmetry, i.e., the lack of inversion symmetry of the underlying crystal, as in zincblende compounds (Winkler, 2003).

The lesson to be learned from this example is not that low-energy effective models of Rashba or Dresselhaus type are unreliable—quite the contrary, they are pillars of spintronics, even if more complex models are often needed, e.g., for precise quantitative comparisons with experiments. It is rather that any effect crucially depending on the coupling between orbital motion and internal (spin) dynamics is subtler than standard charge-only transport phenomena, even when their description is based on the simplest models. As a corollary, attacking the problem from different angles—Kubo *vs.* kinetics in this case—can be a good idea.

The Rashba and Dresselhaus scenarios just considered are examples of a standard approach to transport widely employed throughout condensed matter. The latter starts from some low-energy ($\mathbf{k}\cdot\mathbf{p}$) effective model whose parameters can be computed with *ab-initio* methods, or left as symmetry-allowed parameters to be estimated by comparison with experiments. In our case the minimal Hamiltonian for spin 1/2 quasiparticles reads

$$H = H_0 + \mathbf{b}(\mathbf{p}) \cdot \boldsymbol{\sigma} + \delta H \quad (26)$$

where H_0 describes band-bottom (top) free electrons (holes), and $\mathbf{b}(\mathbf{p})$ is the effective intrinsic spin-orbit field, see Eq. (10). Higher-dimensional models (4×4 , $6 \times 6 \dots$) are employed whenever more than a single s-band lie close to the Fermi energy, which is the case, e.g., for graphene (Neto et al., 2009; Kochan et al., 2017; Dyrdał and Barnaś, 2012; Millettari et al., 2017), Pt (Guo et al., 2008) or typically for holes (Engel et al., 2007; Winkler, 2003). On the other hand there are situations in which the term $\mathbf{b}(\mathbf{p})$ is negligible, e.g., in bulk Al or Cu. The last term δH contains all extra ingredients needed in the specific situation, e.g., exchange coupling with a magnetic texture, extrinsic spin-orbit coupling, disorder, phonons and so on.

The effective Hamiltonian (26) is used to study non-equilibrium dynamics with whatever analytical and/or numerical techniques one prefers. The approach is thus very general and flexible. Alternatively, it is also possible to stick to *ab-initio* methods and use an atomistic Hamiltonian throughout. In this case one typically relies on Kubo linear response formalism to compute the relevant transport coefficients, e.g., σ^{sHe} (Lowitzer et al., 2011; Ködderitzsch et al., 2015).

Onsager reciprocity and a non-Abelian gauge field point of view

The sHe and isHe connect spin currents, even under time-reversal, with charge currents, odd under time-reversal. From the general properties of Kubo response functions (Landau et al., 2008) there follows

$$\langle \langle j_y^z, j_x \rangle \rangle = - \langle \langle j_x, j_y^z \rangle \rangle, \quad (27)$$

which implies

$$\sigma^{\text{sHe}} = -\sigma^{\text{isHe}}. \quad (28)$$

This is the (linear response) Onsager relation between the sHe and isHe. It is evident that changing the definition of the spin current changes the value of σ^{sHe} and σ^{isHe} . This is critical if a direct comparison with experiments is sought: what spin current is being excited in the experimental setup? What spin Hall angle are we talking about? As discussed in Section “Phenomenology and basic concepts” there are numerous ways to remove any ambiguity from such a comparison. In particular, if one is not interested in local quantities such as conductivities, the problem can be bypassed by considering conductances between metallic leads without spin-orbit interaction (Jacquod et al., 2012). On the other hand a change of spin current definition does not break Onsager reciprocity if done consistently, i.e., if the same definition is used to describe both the direct, say sHe, and reverse bias, say isHe, scenario.

Another source of concern in the early 2000s was that the standard definition of spin currents, Eq. (14), may yield non-vanishing equilibrium (circulating) currents (Rashba, 2003). Different authors highlighted however that there is nothing intrinsically unphysical or surprising in this (Tokatly, 2008; Sonin, 2007b): spin currents are even under time-reversal, so can exist in equilibrium, and physical systems hosting different kinds of equilibrium currents anyway exist (Tokatly, 2008; Sonin, 2010b, 2007b; Heurich et al., 2003). Indeed, adopting a non-Abelian gauge field point of view, equilibrium spin currents can be identified with the non-Abelian analogous of dissipationless Landau paramagnetic currents in solids (Tokatly, 2008).

The non-Abelian gauge field approach requires to rewrite the spin-orbit interaction in terms of a non-Abelian vector potential $\mathcal{A}$, i.e., a tensor $\mathcal{A}_i^a$ with both spin (a) and real space (i) indices. To be definite, for the Rashba Hamiltonian (16) one has

$$H_R = \frac{(\mathbf{p} + \mathcal{A})^2}{2m} + \text{const.} \quad (29)$$

with $\mathcal{A}_x^y = -\mathcal{A}_y^x = 2m\alpha/\hbar^2$, while $\mathcal{A}_i^a = 0$ for all other components. The spin current immediately follows from $j_i^a = \partial H_R / \partial \mathcal{A}_i^a$. It coincides with the standard definition (14) and generally consists of both transport contributions and a non-dissipative equilibrium part. Pursuing this route, e.g., in a diffusive sample, one obtains in particular a clear parallel between the standard Hall current

$\mathbf{j}_{\text{Hall}}$ in presence of a magnetic field $\mathbf{B}$ and the a -polarized spin Hall current $\mathbf{j}_{\text{He}}^a$ in presence of a non-Abelian pseudomagnetic field $\mathcal{B}$ generated by $\mathcal{A}$ (Gorini et al., 2010)

$$\mathbf{j}_{\text{Hall}} = \frac{q\tau}{m} \mathbf{j} \times \mathbf{B} \rightarrow \mathbf{j}_{\text{He}}^a = \frac{q\tau}{4m} \mathbf{j} \times \mathcal{B}^a. \quad (30)$$

The non-Abelian gauge field approach is based on relatively old ideas (Mathur and Stone, 1992; Fröhlich and Studer, 1993; Brouwer et al., 2002), but was recently revived to describe spin-charge coupled transport in different settings (Gorini et al., 2010; Raimondi et al., 2012; Adagideli et al., 2012; Bergeret and Tokatly, 2013; Tokatly and Sherman, 2016; Tölle et al., 2017; Bobkova and Bobkov, 2017; Jacobsen and Linder, 2017; Mal'shukov, 2017; Aikebaier et al., 2019; König and Levchenko, 2021). While its merits are evident, one should realize that a rewriting like Eq. (29) is not always possible. I refer to the relevant literature for details.

Conclusion

The spin Hall effects are a family of transverse transport phenomena appearing in (pseudo)spin-orbit coupled systems. A good chunk of the theory and experimental background was established in the 1970s–80s, but the effects became widely known in condensed matter only starting from the early 2000s, and are nowadays cornerstones of both fundamental and applied spintronic research. Such a late blooming is probably due in good part to two roughly contemporary events. First, the widespread realization of the importance of geometry/topology-related concepts for Bloch electrons. Since the latter usually require quasiparticles to have an internal structure, this strongly increased interest for (pseudo)spin-orbit coupled dynamics. Second, technological advances which notably allowed the fabrication of high-quality semiconductor heterostructures, where spin manipulation became possible with a high level of precision, soon after followed by the discovery and functionalization of graphene and other materials with strong (pseudo)spin-orbit interaction.

In this short overview I focused on the core, standard forms of the spin Hall effects, as they exist in normal Fermi liquids. In this context they are active in a wide range of parameters, from large samples at room temperature—important for potential applications—down to mesoscopic samples at low temperatures. However they may also appear in, e.g., strongly disordered systems (Smirnov and Golub, 2017), superconductors (Takahashi and Maekawa, 2011), metallic antiferromagnets (Zhang et al., 2014; Gulbrandsen et al., 2020), as “valley Hall effects” in different materials (Gorbachev et al., 2014; Mak et al., 2014; Lensky et al., 2015) or in the propagation of magnons (Onose et al., 2010; Mook et al., 2014) and light (Hosten and Kwiat, 2008). They may also contribute to other transport effects, such as the spin Hall magnetoresistance (Chen et al., 2016, 2013; Oyanagi et al., 2021). In short, they are potentially present in any scenario where transport is due to quasiparticles with some internal structure which couples to a non-trivial background.

Notes on further readings

The literature on the spin Hall effects is vast and ramifies quickly to neighboring subfields. The bibliography given here is meant to provide barebone directions to the newcomer, but is by no means exhaustive. Numerous review articles, each with its own qualities and shortcomings, are available to the interested reader. Dyakonov and Khaetskii (2006) and Engel et al. (2007) are both must-read works. Dyakonov and Khaetskii (2006) provides in particular a thorough historical overview and excellent phenomenological discussions, while Engel et al. (2007) offers a high-quality and very compact introduction to the technical background, introducing also modern topological concepts. I also suggest Fert and Dau (2019) for a recent, short and more application-oriented discussion, and Vignale (2010) for its theory part. Finally, Sinova et al. (2015) provides an excellent experimental overview.

Acknowledgments

I am indebted to Lin Chen for a careful reading of the manuscript and to Leonid E. Golub for useful comments. I also thank all STerQO members for discussions.

Abstract

Torques on magnetization when an electric current is applied to magnets, called the spin torques, are overviewed.

Key points

- History, phenomenology and microscopic description of the spin-transfer torque
- Equation of motion of magnetization including the spin torques
- Touch recent topics

Introduction

The spin-transfer torque is a torque on magnetization (localized spins) induced by applying an electric current.¹ It arises from a transfer of spin angular momentum from driven electrons to the magnetization and is one of the current-induced torques of various origins.

The idea of driving magnetization structure by applying electric current was theoretically studied by Berger (1978). It was discussed theoretically that a magnetic domain wall can be driven by a current due to the counterforce of the electron scattering by the wall. The force is proportional to the resistance due to the wall, and is small in most 3d ferromagnets as domain wall is thick compared to the electron scale, the inverse Fermi wave length. The scattering force represents an exchange of linear momentum, and is different from the spin-transfer effect. In 1986, Berger discussed the effect of spin-transfer, although it was not called so, between a domain wall and electron propagating through it (Berger, 1986). The transfer occurs as a result of a strong *sd* exchange interaction between electron spin and the magnetization, which causes a flip of electron spin as it passes through the wall. The transfer is efficient for a thick wall, and the wall moves with a velocity proportional to the applied current to conserve the total spin angular momentum of the system. The term spin transfer was used by J.C. Slonczewski in the context of current-induced magnetization reversal in a magnetic multilayer (Slonczewski, 1996).

The spin-transfer torque arises from the spatial variation of magnetization (localized spin $S(\mathbf{r})$), and for smooth structure, the torque at the linear-order of the spatial derivative is written as

$$\tau_{\text{st}} = -\frac{a^3}{2eS}(j_s \cdot \nabla)S \quad (1)$$

where j_s is a spin current density, $S \equiv |S|$, a is the lattice constant. The spin-transfer torque arises when electron spin is strongly polarized along the local direction of the magnetization or the local spin, a situation called adiabatic.

The concept of spin-transfer torque was extended later. Zhang and Li (2004) and Thiaville et al. (2005) pointed out that a relaxation of electron spin leads to a torque orthogonal to the spin-transfer torque,

$$\tau_\beta = -\beta \frac{a^3}{2eS}[S \times (j_s \cdot \nabla)S] \quad (2)$$

with a constant β representing the relaxation effect. In most ferromagnetic metals, the dominant origin of the parameter β is the spin-orbit interaction of the conduction electron. The relaxation induces a non adiabatic process, where electron spin deviates from

¹It is sometimes called spin torque, but physical meaning becomes obscure.

the local spin direction, and thus the relaxation-driven current-induced torque is called a non adiabatic (spin-transfer) torque or β -torque after Thiaville et al. The two orthogonal torques, τ_{st} and τ_{β} , are complete to describe any torque conserving the magnitude of the localized spin. Later, current-induced torques in systems with strong spin-orbit interaction, called spin-orbit torques (Manchon et al., 2019), were investigated, such as the torque arising from the Rashba interaction at interfaces and the torque due to a spin Hall effect in bilayers of a heavy metal and a ferromagnet. As the main source of electron spin relaxation represented by the parameter β is the spin-orbit interaction, the non adiabatic torque is a spin-orbit-induced torque in a broad sense. In the recent literature, spin-orbit torque often refers to the case with spin-orbit interaction having particular symmetry, such as the Rashba interaction breaking the inversion symmetry.

Spin-transfer mechanism

• Smooth magnetic structure

For electron propagation through a smooth magnetic structure, the efficiency of the spin-transfer effect is 100% in the adiabatic limit, where the electron spin has enough time to rotate during the propagation through a magnetic structure. For the case of a domain wall with thickness λ_w , the adiabatic condition is (Waintal and Viret, 2004)

$$\frac{\lambda_w}{v_F} \gg \frac{\hbar}{J_{sd}}, \quad (3)$$

where $\hbar/J_{sd}$ is the time for electron spin rotation (J_{sd} being the energy for the sd exchange coupling between the localized spin and conduction electron spin), λ/v_F is the time for electron with Fermi velocity $v_F (= \hbar k_F/m)$ to pass through the wall k_F and m being the Fermi wave vector and the electron mass, respectively.² In the adiabatic limit, the electron spin gets rotated after passing through the wall, and the change of spin angular momentum, $2 \times \frac{\hbar}{2} = \hbar$, must be absorbed by the localized spins if dissipation is neglected. To absorb the spin change of $\hbar$, the domain wall must shift by a distance $\Delta X = [\hbar/(2\hbar S)]a$ (a is the lattice constant) (Fig. 1). When we apply a constant electric current density j with spin polarization rate P , i.e., a spin current density of $j_s = Pj$, the rate of the angular momentum change of the conduction electron per unit time and area is $\hbar j_s$. As the number of the localized spins in the unit area is $1/a^2$, the wall must keep moving a distance of $j_s(a^3/2S)$ per unit time. Namely, when a spin current density is applied, the wall moves with the speed.

$$v_{st} \equiv \frac{a^3}{2S} j_s. \quad (4)$$

This is the velocity of a domain wall when spin-transfer efficiency is 100%. It is notable that the spin-transfer effect acts on any magnetic structures if smooth, and drives them at the same velocity v_{st} .

• Ferromagnetic bilayer (Fig. 2)

In the case of two ferromagnetic metallic thin films with a metallic spacer or tunneling barrier between the ferromagnetic layers, the electron spin is subject to a sudden change of the localized spin. An injected current gets spin-polarized by the first magnetic layer (fixed layer) and exerts a torque on the second magnetic layer (free layer). The nonequilibrium spin polarization of the electron injected to the second layer is written as $g_{st}I_e(S_1 \times S_2)$, where I_e is the injected current, S_1 and S_2 are the magnetization of the first and the second layer, respectively, and g_{st} is an efficiency constant determined by the structure. The torque acting on the second layer is thus.

Fig. 1 Schematic figure describing the spin-transfer effect by a domain wall. Electron spin (small arrow with a sphere) is directed along the direction of localized spin (large arrows) by a strong exchange coupling. For a thick wall, the electron spin passing through the wall is therefore flipped (the adiabatic limit), resulting in the angular momentum change of $\frac{\hbar}{2} \times 2 = \hbar$. The shift of the domain wall by a distance ΔX results in a change of the spin of the localized spins $\frac{\Delta X}{a}S - (-\frac{\Delta X}{a}S) = 2S\frac{\Delta X}{a}$ (a and S are the lattice constant and magnitude of spin, respectively). The displacement needed to compensate the angular momentum of electron spin is therefore $\Delta X = \frac{a}{2S}$. Each electron passing through the wall shifts the wall by a distance ΔX .

²In dirty metals, it is modified (Stern, 1992).

Fig. 2 The spin-transfer effect in a multilayer of two ferromagnetic films. An electron current injected from the bottom get polarized by the lower layer magnetization $\mathbf{S}_1$ and drives the top layer magnetization $\mathbf{S}_2$.

$$\boldsymbol{\tau}_{\text{bilayer}} = g_{\text{st}} I_e [\mathbf{S}_2 \times (\mathbf{S}_1 \times \mathbf{S}_2)], \quad (5)$$

which tends to align $\mathbf{S}_2$ along the direction $\mathbf{S}_1$. When $\mathbf{S}_1$ and $\mathbf{S}_2$ are close, $\mathbf{S}_2 \simeq \mathbf{S}_1 + \mathbf{d} \cdot \nabla \mathbf{S}_1$ ($\mathbf{d}$ is a vector representing the layer distance), and the expression reduces to the spin-transfer torque $\boldsymbol{\tau}_{\text{st}}$ for a smooth magnetization structure.

Equation of motion

The equation of motion for spin $\mathbf{S}$ under a magnetic field $\mathbf{B}$ is called the Landau-Lifshitz-Gilbert (LLG) equation, which reads

$$\dot{\mathbf{S}} = \gamma \mathbf{S} \times \mathbf{B} - \frac{\alpha}{S} \mathbf{S} \times \dot{\mathbf{S}} \quad (6)$$

where γ is the gyromagnetic ratio and $\alpha(\geq 0)$ is the Gilbert damping constant (usually $\alpha \ll 1$) and $S \equiv |\mathbf{S}|$. For localized spins with a spatial distribution, $\mathbf{S}(\mathbf{r}, t)$, the equation remains the same if the magnetic field includes the ones arising from the interactions, such as the exchange interaction and anisotropy energy. Taking account of the current-induced torques, the equation becomes

$$\dot{\mathbf{S}} = \gamma \mathbf{S} \times \mathbf{B} - \frac{\alpha}{S} \mathbf{S} \times \dot{\mathbf{S}} - \frac{a^3}{2eS} (\mathbf{j}_s \cdot \nabla) \mathbf{S} - \frac{a^3}{2eS} \beta [\mathbf{S} \times (\mathbf{j}_s \cdot \nabla) \mathbf{S}] + \boldsymbol{\tau}_{\text{na}} \quad (7)$$

Here $\boldsymbol{\tau}_{\text{na}}$ represents a nonadiabatic torque that is higher order in the spatial derivative, such as the effect of the electron reflection force.

The role of the spin-transfer torque is clearly seen in the case of a domain wall. Considering a one-dimensional domain wall structure of $\mathbf{S}(x, t) = S(\sin\theta \cos\phi, \sin\theta \sin\phi, \cos\theta)$ with $\cos\theta(x, t) = \tanh[(x - X(t))/\lambda]$ and a time-dependent angle of the wall plane, $\phi(t)$, the equation of motion reduces to a coupled equations for the two coordinates,

$$\dot{X} - \alpha \dot{\phi} = -v_c \sin 2\phi + \frac{a^3 P}{2eS} j \quad (8)$$

$$\dot{\phi} + \alpha \frac{\dot{X}}{\lambda} = \frac{\bar{\beta}}{\lambda} \frac{a^3 P}{2eS} j \quad (9)$$

where v_c is a constant proportional to the hard-axis magnetic anisotropy energy and $\bar{\beta} = \beta + \beta_{\text{na}}$ with β_{na} is the contribution from $\boldsymbol{\tau}_{\text{na}}$ representing the reflection force, which is proportional to the resistivity due to the wall (Tatara et al., 2008). The equations clearly indicates that the spin-transfer effect contributes to a velocity of the wall $\dot{X}$, while the non-adiabatic torques (β and $\boldsymbol{\tau}_{\text{na}}$) contribute to the equation for $\dot{\phi}$, which represents the force on the wall.

Microscopic theory

The spin-transfer effect for smooth structures is elegantly described by a microscopic theory. For spin of the injected electron having a strong exchange coupling to localized spin, a spatially-changing smooth magnetization structure acts as an effective gauge field as seen in the following argument Tatara (2019). An electron with mass m interacting with localized spin $\mathbf{S}$ by a strong exchange interaction J_{sd} is described by the Schrödinger equation,

$$\left(-\frac{\hbar^2}{2m} \nabla^2 - M \mathbf{n}(\mathbf{r}) \cdot \boldsymbol{\sigma} \right) |\Psi\rangle = i\hbar \frac{\partial}{\partial t} |\Psi\rangle, \quad (10)$$

where $M = J_{sd} S$ is the spin polarization, $\mathbf{n} \equiv \mathbf{S}/S$ and $|\Psi\rangle$ is a wave function with two spin components, $\boldsymbol{\sigma}$ being the vector of three Pauli matrices. The spatially-varying energy due to magnetization modulation is removed by a local unitary transformation to choose spin quantization axis along the localized spin introducing a 2×2 transformation matrix $U(\mathbf{r})$ satisfying $U^{-1}(\mathbf{n} \cdot \boldsymbol{\sigma})U = \sigma_z$. For a localized spin configuration described by a polar coordinate fields $(\theta(\mathbf{r}), \phi(\mathbf{r}))$, i.e., $\mathbf{n} = (\sin\theta \cos\phi, \sin\theta \sin\phi, \cos\theta)$, a choice of U is $U = e^{-\frac{i}{2}\phi\sigma_z} e^{-\frac{i}{2}\theta\sigma_y} e^{-\frac{i}{2}(\pi-\phi)\sigma_z}$. The Schrödinger equation in the rotated frame state, defined as $|\phi\rangle \equiv U^{-1} |\Psi\rangle$ is

$$\left[-\frac{\hbar^2}{2m} (\nabla - i\mathcal{A}_s)^2 - M\sigma_z \right] |\phi\rangle = i\hbar \frac{\partial}{\partial t} |\phi\rangle, \quad (11)$$

where $\mathcal{A}_s \equiv -iU^{-1}\nabla U$ is a 2×2 matrix representing an effective gauge field. For large exchange coupling, the up-spin ($\uparrow$) component with lower energy survives (the adiabatic limit), and the gauge field reduces to a single component ($U(1)$) gauge

field $\mathbf{A}_s \equiv (\mathcal{A}_s)_{\uparrow\uparrow}$, which explicitly reads $\mathbf{A}_s = \frac{1}{2}(1 - \cos \theta)\nabla\phi$. The background of localized spin configuration is thus represented by an effective gauge field coupling to a spin-polarized current $\mathbf{j}_s$ by a gauge coupling $H_{A_s} = -\mathbf{A}_s \cdot \mathbf{j}_s$, neglecting the second-order spatial derivative. The gauge coupling describes an interaction on the localized spin, as $\mathbf{A}_s$ is a function of localized spin direction. The dynamics of localized spin with Hamiltonian H_S is described by the Landau-Lifshitz equation derived from the Lagrangian $L_S = -\hbar S(1 - \cos \theta)\dot{\phi} - H_S$. When coupled to the conduction electron, the Lagrangian includes H_{A_s} to be

$$L_S - H_{A_s} = -\hbar S(1 - \cos \theta)(\partial_t - \mathbf{v}_{st} \cdot \nabla)\phi - H_S \quad (12)$$

where $\mathbf{v}_{st} = \frac{a^3}{2S}\mathbf{j}_s$ is a velocity due to the spin-transfer torque. The Lagrangian is Galilean invariant, meaning that any magnetization structure flows with the velocity $\mathbf{v}_{st}$, consistent with a phenomenological argument.

Spin-orbit torque

Spin-orbit torques are current-induced torques where spin-orbit interaction for the electron is essential. The torque acting on the localized spin $\mathbf{S}$ (or magnetization) depends strongly on the spin-orbit interaction and symmetry. Conventionally it is decomposed into two independent directions as

$$\boldsymbol{\tau}_{\text{sot}} = \eta_{\text{FL}} \mathbf{S} \times \boldsymbol{\zeta} + \eta_{\text{DL}} [\mathbf{S} \times (\mathbf{S} \times \boldsymbol{\zeta})], \quad (13)$$

where $\boldsymbol{\zeta}$ is essentially a spin density induced by the spin-orbit interaction and localized spin under a current. The component with coefficient η_{FL} is called the field-like torque, as it represents an effective magnetic field proportional to $\eta_{\text{FL}}\boldsymbol{\zeta}$, and the one with η_{DL} is called the damping-like torque as it points the same direction as the damping torque in the Landau-Lifshitz equation. Spin-orbit torques are often discussed for multilayers of a ferromagnet and a nonmagnetic heavy metal, where the applied current and the spin-orbit interaction in the heavy metal induces interface spin accumulation and torque. Various origins of spin-orbit torques have been argued, such as spin Hall effect, Rashba spin-orbit interaction, the inverse spin galvanic effect (Manchon et al., 2019), but what matters in any cases is the current-induced spin accumulation formed at the interface to the ferromagnetic layer.

Antiferromagnets and other systems

The concepts of spin-transfer torque and spin-orbit torque have been extended to the case of antiferromagnets, ferrimagnets, and topological insulators (Jungwirth et al., 2016; Baltz et al., 2018; Manchon et al., 2019).

Conclusion

History and phenomenological theory the spin-transfer torque was overviewed and a microscopic description was introduced. The Equation of motion of magnetization including the spin torques was argued. Recent topics were briefly touched.

Abstract

Quantum magnonics concerns quantum states of magnons and the interplay between magnon spintronics, and quantum information science. It is a highly interdisciplinary field that combines spintronics, quantum optics, and quantum information. In this chapter, we will first introduce magnon quantum states, including magnon antibunching and squeezed states. Macroscopic quantum phenomena including spin superfluidity and Bose–Einstein condensation will also be briefly covered. Hereafter, we discuss the integration of magnonic systems with mature quantum platforms, including photonic cavities, qubits, and phononic systems, together with the applications of hybrid magnonic systems. Finally, we present an outlook on the opportunities and challenges for quantum magnonics.

Introduction

Finding efficient means to store and process big data is a central topic in modern society due to the rapid accumulation of information in science, technology, economics, and social activities. To overcome the large energy consumption and Joule heating problems of the traditional transistor technologies, spintronics, and quantum information science stand out and have been innovating the concepts of information processing over the past few decades. Spintronics emerged in the late 1980s and focuses on the manipulation of the spin of an electron, instead of its charge that is exploited in conventional electronics (Hirohata et al., 2020). Here, the information is coded in the direction of the spin as well as in the spin excitations, so-called magnons. Magnon spintronics, a subfield of spintronics, focuses on the generation, manipulation, and read-out of magnons for information processing (Chumak et al., 2015). Magnons can propagate in a magnetic insulator over long distances as a result of the low dissipation of insulating magnets, which can significantly reduce the energy consumption for information processing. On the other hand, quantum computing and quantum information science manipulate the quantum nature of spins and utilize the basic principles of quantum mechanics, such as superposition and entanglement, as a resource for computation and communication (Nielsen and Chuang, 2000). As an example, a spin-1/2 system has two degrees of freedoms and can thus represent a quantum bit. Different from a classical bit, a quantum bit or qubit is able to be in any quantum superposition of spin up and down. By integrating and manipulating many qubits coherently, the information can be processed in a more efficient and secure way (Arute et al., 2019).

Recently, the developments of magnon spintronics and quantum information have begun to overlap with each other because of the significant progress toward the understanding of the entanglement properties of quasiparticles such as photons, magnons, and phonons. Furthermore, with the advancement of material science, magnonic systems can be readily integrated with well-established quantum platforms to achieve multi-functional quantum information processing. This concerns, for example, cavity photons, superconducting qubits, and mechanical oscillators, coupled to magnonic systems. From these endeavors, the highly interdisciplinary field of quantum magnonics has emerged (Yuan et al., 2022a), which combines the concepts of magnon spintronics, quantum optics and quantum information science, and has the potential to give the development of traditional magnonics new directions.

In general, the framework of quantum magnonics includes the manipulation of quantum states of magnons and the integration of magnonic platforms with known quantum systems such as cavity photons, qubits, and phonons, as shown in Fig. 1. More broadly, macroscopic quantum phenomena including magnon Bose–Einstein condensation (BEC) and spin superfluidity also belong to the realm of quantum magnonics. In this chapter, we will first introduce the basic concepts that are involved with magnons and then follow the framework of Fig. 1 to introduce magnon quantum states as well as the hybrid quantum systems

Fig. 1 Framework of quantum magnonics. The central route studies quantum states of magnons at low temperatures. The left route integrates magnons with phonons corresponding to lattice vibrations of a magnet or mechanical vibrations of external oscillators. The top route entangles magnons with photons ranging from optical down to microwave frequency. The right route couples magnons to discrete variable systems including superconducting qubits and single-spin qubit (nitrogen-vacancy centers, silicon-vacancy centers, etc.). based on magnets. Finally, we give a summary and outlook for quantum magnonics. Unless stated otherwise, we decorate operators with a hat and set the reduced Planck constant equal to one.

Spin waves and magnons

It is known that a spin precesses around an external field and, in addition, relaxes toward this field due to its interaction with the environment. In ordered magnets, many spins are tied together through short-range exchange interactions and long-range dipolar interactions. As a result, the motion of one spin will force the motion of its neighbors and results in a wave-like pattern of spin excitation, so-called spin waves, as shown in Fig. 2A. A spin-wave mode is characterized by its frequency ω and, when the system is homogeneous, wavevector $\mathbf{k}$. The exchange interaction usually dominates the properties of spin waves with short wavelength while dipolar interaction is important for spin waves with long wavelength, as shown in Fig. 2B. To fully quantify the spin-wave dispersion, one has to solve the Maxwell equations coupled to the equation for classical magnetization dynamics. The resulting dispersion depends on the magnetization orientation and geometry of the magnet (Kalinikos and Slavin, 1986).

In quantum mechanics, a spin state is fully represented by the spin operator $\hat{S}$ and its component along the quantization axis $\hat{S}_z$ as

$$\hat{S}^2|S, m\rangle = S(S+1)|S, m\rangle, \quad \hat{S}_z|S, m\rangle = m|S, m\rangle, \quad (1)$$

where the excitation of one magnon corresponds to the reduction of S_z by a quantum of angular momentum $\hbar$, as shown in Fig. 2C. Within this approach, it is not easy to treat the interaction between many spins and magnons. Holstein and Primakoff first noticed that (Holstein and Primakoff, 1940) the possible values of m can be rewritten as $m = S - n$ with $n = 0, 1, 2, \dots, 2S$. In the new basis, we have $\hat{S}_z|S, n\rangle = (S - n)|S, n\rangle$. By comparing with the quantization of a harmonic oscillator, we readily have the second quantization form of $\hat{S}_z$ as $\hat{S}_z = S - \hat{a}^\dagger \hat{a}$, where $\hat{a}$ ($\hat{a}^\dagger$) is the annihilation (creation) operator of a spin quantum or a magnon. To show how to preserve the commutation relations for angular momentum $[\hat{S}_i, \hat{S}_j] = i\epsilon_{ijk}\hat{S}_k$, where ϵ_{ijk} is the Levi-Civita symbol, we recall the spin raising and lower operators defined as $\hat{S}^\pm = \hat{S}_x \pm i\hat{S}_y$. From the properties of angular momentum, we have

$$\hat{S}^+|S, n\rangle = \sqrt{2S - (n - 1)}\sqrt{n}|S, n - 1\rangle = \sqrt{2S - \hat{a}^\dagger \hat{a}}\hat{a}|S, n\rangle. \quad (2)$$

Fig. 2 (A) Schematic of magnetic-moment precession and spin-wave excitation in a classical picture. (B) Typical spin-wave dispersion of a finite ferromagnetic body. With the increase of wave number k , dipolar, dipolar exchange, and exchange spin waves are classified. (C) Relation between magnon excitation and a reduction of magnetic component along the quantization axis in the quantum picture. For $S = 1/2$, magnon excitation corresponds to flipping a single spin.

We therefore derive

$$\hat{S}^+ = \sqrt{2S - \hat{a}^\dagger \hat{a}} \hat{a}, \quad \hat{S}^- = (\hat{S}^+)^\dagger = \hat{a}^\dagger \sqrt{2S - \hat{a}^\dagger \hat{a}}. \quad (3)$$

The combined transformation of $\hat{S}_z$ and $\hat{S}^\pm$ allows us to express the excitation of a single spin $\hat{S}$ in terms of magnon creation and annihilation operators, and is widely used to describe the interaction of magnons and the interaction between spin systems and other physical systems.

We have discussed the quantization of a single spin and how to introduce operators that describe magnons. A real magnet, however, is composed of many spins interacting with each other through exchange and dipolar interactions, and the spins themselves may have preferred orientations due to spin-orbit coupling. Depending on the competition of these interactions, the ground state of a magnet may be collinear or correspond to noncollinear magnetic textures such as domain walls, vortices, and skyrmions. To consider magnon excitations on top of a particular ground state, one can apply the Holstein-Primakoff (HP) transformation on the spin texture of the system and, in principle, derive an effective Hamiltonian including any order of magnon-magnon interaction. As an example, let us consider a biaxial magnet subject to an external field $\mathbf{H} = H\mathbf{e}_z$. The Hamiltonian reads

$$\hat{\mathcal{H}} = -J \sum_{\langle i,j \rangle} \hat{\mathbf{S}}_i \cdot \hat{\mathbf{S}}_j + K_x \sum_i (\hat{S}_{i,x})^2 - K_z \sum_i (\hat{S}_{i,z})^2 - \mu_0 g_e \mu_B H \sum_i \hat{S}_{i,z}, \quad (4)$$

where J is the exchange coefficient and the first sum is over the neighboring spins, the second and third terms represent the magnetic anisotropies with anisotropy coefficients K_x and K_z , and the last term is Zeeman energy. μ_0 , g_e , and μ_B are vacuum susceptibility, Landé g -factor, and Bohr magneton, respectively. We consider the case $K_x > 0$, $K_z > 0$, and $H > 0$ such that the classical ground state of the system obeys $\langle \hat{\mathbf{S}} \rangle = S\mathbf{e}_z$.

By employing the HP transformation of the spin operators for this ground state, we have

$$\hat{\mathcal{H}} = -JS \sum_{\langle i,j \rangle} (\hat{a}_i^\dagger \hat{a}_j^\dagger + h.c.) + \sum_i \mu_i \hat{a}_i^\dagger \hat{a}_i + \frac{K_x S}{2} \sum_i (\hat{a}_i^\dagger \hat{a}_i + h.c.) + \hat{\mathcal{H}}^{(3)} + \hat{\mathcal{H}}^{(4)} + \dots, \quad (5)$$

where $\hat{a}_i$ ($\hat{a}_i^\dagger$) is the magnon annihilation (creation) operator on the i th site, $\mu_i = 2ZJS + \mu_0 g_e \mu_B H + 2K_z S + K_x S$ with Z being the coordination number. $\hat{\mathcal{H}}^{(3)}$ and $\hat{\mathcal{H}}^{(4)}$ refer to three and four magnon processes, respectively. For a macroscopic magnet far below the Curie temperature, the number of magnon excitations is very small, that is $\langle \hat{a}_i^\dagger \hat{a}_i \rangle \ll S$, such that the interactions between magnons proportional to higher orders of $\langle \hat{a}_i^\dagger \hat{a}_i \rangle / S$ can be safely neglected. By switching to Fourier space and diagonalizing the Hamiltonian,

we finally find the effective Hamiltonian for magnon excitations as $\hat{\mathcal{H}} = \sum_k \omega_k \hat{a}_k^\dagger \hat{a}_k$, where the dispersion of the magnons in the long-wavelength limit $kd \ll 1$ reads

$$\omega_k = \sqrt{[2JS(kd)^2 + \mu_0 g_e \mu_B H + 2K_x S]} \times \sqrt{[2JS(kd)^2 + \mu_0 g_e \mu_B H + 2K_z S + 2K_x S]}, \quad (6)$$

where d is the lattice constant. The ferromagnetic resonance mode with $k = 0$ has the frequency

$$\omega_a = \sqrt{[\mu_0 g_e \mu_B H + 2K_x S][\mu_0 g_e \mu_B H + 2K_z S + 2K_x S]}. \quad (7)$$

For a magnetic sphere, as is widely used in cavity spintronics, $K_x = K_y = 0$, the resonance frequency is $\omega_a = \mu_0 g_e \mu_B H$. The tunability of the magnon frequency through external fields is a main advantage of hybrid magnonic systems.

Quantum states of magnons

In the traditional set-ups involving magnons, they are usually excited by strong microwaves at room temperature. The quantum aspects of the generated magnons are washed out by the thermal fluctuations. As we lower the temperature, it is expected that one can suppress the thermal effects and find quantum states of magnons, in analogy with photonic systems. Up till now, magnon antibunching, squeezed states, and Schrödinger cat states have been theoretically proposed, but remain a challenge to be experimentally verified. The exception is the single magnon excitation in a magnetic sphere, which has been detected by entangling it with a superconducting qubit (Lachance-Quirion et al., 2020), as we discuss below. In this section, we mainly introduce magnon antibunching and the magnon squeezed state.

Magnon antibunching

In the absence of driving, the excited magnons in a magnet will reach equilibrium with the environment and form a thermal magnon gas. The thermal state is well described by a super-Poissonian distribution, which is characterized by the mean magnon number being smaller than the variance of the magnon number. Under strong driving, the magnon gas will reach a coherent state, with mean magnon number equal to its variance. Coherent magnons usually behave classically. To manifest quantum effects of magnons, one can use magnon nonlinearities to generate exotic distributions of the magnon gas. One example is the magnon antibunching, which corresponds to a sub-Poissonian distribution with mean magnon number larger than the magnon number variance. A perfect antibunched magnon gas has large occupation of the first-excited state of the magnons, while the higher order excitations are zero. In general, these states are characterized by a zero-delay second-order correlation function defined as

$$g^{(2)}(0) \equiv \frac{\langle \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} \rangle}{\langle \hat{a}^\dagger \hat{a} \rangle^2} = 1 + \frac{\langle (\Delta \hat{n})^2 \rangle - \langle \hat{n} \rangle}{\langle \hat{n} \rangle^2}, \quad (8)$$

where $\hat{n} = \hat{a}^\dagger \hat{a}$ is the magnon number operator, $\Delta \hat{n} = \hat{n} - \langle \hat{n} \rangle$ is the variance of the magnon number, and $\langle \hat{A} \rangle \equiv \text{tr}(\hat{\rho} \hat{A})$ is the ensemble average of the observable $\hat{A}$. Three regimes are distinguished according to the value of $g^{(2)}(0)$ (Plenio and Knight, 1998): (i) When the magnon distribution is super-Poissonian, $\langle (\Delta \hat{n})^2 \rangle > \langle \hat{n} \rangle$, then $g^{(2)}(0) > 1$. For example, a thermal state has $g^{(2)}(0) = 2$. (ii) When the magnon distribution is Poissonian, for example, a coherent state, one has $\langle (\Delta \hat{n})^2 \rangle = \langle \hat{n} \rangle$ and thus $g^{(2)}(0) = 1$. A magnonic system under strong driving falls into this class. (iii) When the magnon distribution is sub-Poissonian, $\langle (\Delta \hat{n})^2 \rangle < \langle \hat{n} \rangle$ and $g^{(2)}(0) < 1$, implying antibunched magnons. This is a purely quantum mechanical state that cannot be captured by classical statistics (Reid and Walls, 1986). The limiting case $g^{(2)}(0) = 0$ corresponds to a perfect single-magnon source. This phenomenon is also called magnon blockade because only one magnon is allowed to be excited and all the other magnon excitations are blocked.

The conventional method to generate magnon antibunching is to enhance the Kerr nonlinearity ($\hat{a}^\dagger \hat{a}^2$) of the magnonic system. To illustrate this point, let us recall the effective Hamiltonian of a biaxial magnet as shown in Fig. 3A and include the magnon–magnon interaction as

$$\hat{\mathcal{H}} = \omega_a \hat{a}^\dagger \hat{a} + w(\hat{a}^\dagger \hat{a}^\dagger + \hat{a} \hat{a}) + v(\hat{a}^\dagger \hat{a})^2 + u(\hat{a}^\dagger \hat{a} \hat{a} + \hat{a}^\dagger \hat{a}^\dagger \hat{a}) + \zeta(\hat{a} e^{i\omega_d t} + \hat{a}^\dagger e^{-i\omega_d t}), \quad (9)$$

where $\omega_a = 2K_z + K_x + \mu_0 g_e \mu_B H$, $w = K_x S/2$, $v = -K_z/N - K_x/2N$, $u = -K_x/4N$, with N being the number of spins in the magnet. Here the nonlinear terms u and v may come from either dipolar interactions or magnetocrystalline anisotropy. Since they are inversely proportional to the number of spins in the system, reducing the size of the magnet strengthens the nonlinearity, leading to anharmonic energy levels, as shown in Fig. 3B. By carefully choosing the microwave frequency $\omega_d = \omega_1 - \omega_0$, it will efficiently pump the magnons to the first energy level but cannot excite them further due to the frequency mismatch (Yuan and Duine, 2020). Therefore, magnon antibunching may be realized. A typical phase diagram of the system in the $(K_x S/2\gamma, K_z/\gamma N)$ plane is shown in Fig. 3C, with γ being the gyromagnetic ratio. Clearly, as the size of the nanomagnet is scaled down to the several nanometers, the second-order correlation function becomes smaller than one, indicating the existence of magnon antibunching.

Another way to induce anharmonicity of the magnon energy levels is to couple the magnon mode to an ancillary mode. For example, a superconducting qubit can dress the energy levels of the magnons due to their coupling (Liu et al., 2019). As a result, one

Fig. 3 (A) Schematic of a nanomagnet with spin polarized along the z-axis. (B) Anharmonic energy-level distribution of the magnet with strong nonlinearities. The excitation of a magnon from $n = 1$ to 2 by a microwave with frequency $\omega_1 - \omega_0$ will be suppressed due to the frequency mismatch. (C) Second-order correlation function $g^{(2)}(0)$ of magnons as a function of $K_x S / 2\gamma$ and $K_z S / \gamma N$. The orange balls sketch typical magnetic spheres with bunched and antibunched behavior. Adapted from Yuan HY and Duine RA (2020) Magnon antibunching in a nanomagnet. *Physical Review B* 102(10): 100402. <https://doi.org/10.1103/Phys-RevB.102.100402>.

can properly choose the driving field to generate antibunched magnons. Besides, one can use interference effects between different quantum channels to enhance the occupation of the single-magnon energy level (Wang et al., 2020), even in the absence of nonlinearities. To detect the antibunched magnons, one can couple the magnonic system to photons or qubits and then read the state of these ancillary modes to deduce the quantum states of the magnons.

Squeezed states

The Heisenberg uncertainty principle states that the product of quantum fluctuations of two noncommuting observables has a lower bound determined by the reduced Planck constant $\hbar$. However, it is possible to realize a state with quantum noise in one observable below the symmetric limit at the expense of increased fluctuations in the other observable. Such states are called squeezed states and have been realized in photonic systems. By denoting the photon annihilation and generation operator as $\hat{a}$ and $\hat{a}^\dagger$, the position and momentum operator of photons can be defined as $\hat{x} = (\hat{a} + \hat{a}^\dagger)/\sqrt{2}$ and $\hat{p} = -i(\hat{a} - \hat{a}^\dagger)/\sqrt{2}$. A squeezed state of a photon means that either the uncertainty of $\hat{x}$ or $\hat{p}$ is reduced below $\hbar/\sqrt{2}$. Magnons, as bosons, share similarities with photons. By comparing the definition of position and momentum of photons with the HP transformation of magnons, we immediately find that the position and momentum of magnons are equivalent to the spin components $\hat{S}_x$ and $\hat{S}_y$, respectively. Therefore a squeezed state of magnons can be interpreted as a state with the spin fluctuations in a direction perpendicular to the quantized axis (x or y here) reduced below the symmetric quantum limit $\hbar/\sqrt{2}$.

The minimum model that generates squeezed magnons is the biaxial magnet described in Eq. (4). The effective Hamiltonian of the uniform mode ($\mathbf{k} = 0$) without considering the magnon-magnon interaction reads $\hat{\mathcal{H}}_{\text{FM}} = \omega_a \hat{a}^\dagger \hat{a} + w(\hat{a}^\dagger \hat{a}^\dagger + \hat{a} \hat{a})$. The ground state of the system is a single-mode squeezed state $|\text{GS}\rangle = \exp(r/2(\hat{a} \hat{a} - \hat{a}^\dagger \hat{a}^\dagger))|0\rangle$ with squeezing parameter $r = \text{arctanh}(2w/\omega_a)/2 > 0$. In the magnon number basis, this state is expanded as

$$|\text{GS}\rangle = \frac{1}{\sqrt{\cosh r}} \sum_{n=0}^{\infty} (-\tanh r)^n \frac{\sqrt{(2n)!}}{2^n n!} |2n\rangle, \quad (10)$$

which only contains states with an even magnon number. The uncertainties in the total spin components $\hat{S}_x = \sum_i \hat{S}_i^x$ and $\hat{S}_y = \sum_i \hat{S}_i^y$ in this ground state are readily evaluated as $\Delta S_x \equiv \sqrt{\langle \hat{S}_x^2 \rangle - \langle \hat{S}_x \rangle^2} = e^{-r} \sqrt{NS/2}$ and $\Delta S_y \equiv \sqrt{\langle \hat{S}_y^2 \rangle - \langle \hat{S}_y \rangle^2} = e^r \sqrt{NS/2}$. It is clear that the noise of $\hat{S}_x$ is squeezed below the symmetric limit at the sacrifice of an increase in uncertainty in the $\hat{S}_y$ component. At finite temperatures, one has to consider the relaxation and pure dephasing of magnons to recover the correct equilibrium state (Yuan et al., 2022b). In general, the uncertainty of spin components will keep increasing with temperature and finally exceed the symmetric limit at a temperature of several Kelvin. As a comparison, the elliptical precession of spins, even though it also originates from the in-plane anisotropy, is a classical phenomenon that is insensitive to the temperature.

The concept of magnon squeezing can be extended to the multimode case, which allows us to study the entanglement properties of magnons. As an example, we consider a two-sublattice antiferromagnet (AFM) described by the Hamiltonian

$$\hat{\mathcal{H}}_{\text{AFM}} = J \sum_{j, \delta} \hat{\mathbf{S}}_j \cdot \hat{\mathbf{S}}_{j+\delta} - K_z \sum_j (\hat{S}_j^z)^2 - \sum_j \mathbf{H} \cdot \hat{\mathbf{S}}_j, \quad (11)$$

where $J > 0$ is the AFM exchange coupling between neighboring spins and $K_z > 0$ is the strength of easy-axis anisotropy. Again, we apply an external field along the z -axis ($\mathbf{H} = H\mathbf{e}_z$) to tune the magnon frequency. When the field is below the spin-flop transition field, the spins on the two sublattices are antiparallel to each other to guarantee the ground state is a Néel state, that is, $\langle \hat{\mathbf{S}}_{2l} \rangle = S\mathbf{e}_z$, $\langle \hat{\mathbf{S}}_{2l+1} \rangle = -S\mathbf{e}_z$. Employing the standard HP transformation on the two sublattices, we quantize the magnon excitation above this ground state as

$$\hat{\mathcal{H}}_{\text{AFM}} = \omega_a \hat{a}^\dagger \hat{a} + \omega_b \hat{b}^\dagger \hat{b} + g_{ab}(\hat{a}^\dagger \hat{b}^\dagger + \hat{a}\hat{b}), \quad (12)$$

where $\omega_{a,b} = H_{\text{ex}} + H_{\text{an}} \pm H$, $H_{\text{ex}} = 2ZJS^2$, $H_{\text{an}} = 2K_z S$, and $g_{ab} = H_{\text{ex}}$ is the coupling of magnon modes excited on the two sublattices.

We diagonalize the antiferromagnetic Hamiltonian $\mathcal{H}_{\text{AFM}}$ in Eq. (12) by introducing two Bogoliubov modes $\hat{\alpha} = \cosh \theta \hat{a} + \sinh \theta \hat{b}^\dagger$, $\hat{\beta} = \sinh \theta \hat{a}^\dagger + \cosh \theta \hat{b}$, where $\tanh 2\theta = -2g_{ab}/(\omega_a + \omega_b)$. In terms of the boson operators, $\hat{\alpha}$, $\hat{\beta}$, the Hamiltonian (12) is rewritten as

$$\mathcal{H}_{\text{AFM}} = \omega_\alpha \hat{\alpha}^\dagger \hat{\alpha} + \omega_\beta \hat{\beta}^\dagger \hat{\beta}, \quad (13)$$

where $\omega_{\alpha,\beta} = \pm H + H_{\text{sp}}$ represent the optical and acoustic magnon bands, respectively, and $H_{\text{sp}} = \sqrt{H_{\text{an}}(H_{\text{an}} + 2H_{\text{ex}})}$ is the spin-flop field of the system. We notice that, by employing the two-mode squeezing operator $S(\theta) = \exp[\theta(\hat{a}\hat{b} - \hat{a}^\dagger \hat{b}^\dagger)]$, the magnon eigenmodes are reformulated as $\hat{\alpha} = S(\theta)\hat{a}S^\dagger(\theta)$, $\hat{\beta} = S(\theta)\hat{b}S^\dagger(\theta)$, and thus the joint ground state of the $\hat{\alpha}$ and $\hat{\beta}$ modes is a two-mode squeezed state $|\theta\rangle = S(\theta)|0_a, 0_b\rangle$ (Kamra et al., 2019; Yuan et al., 2020b), where $|0_a, 0_b\rangle$ is the joint vacuum of the magnon modes a and b . Here the two-mode squeezing means that the fluctuations of the total spin component $\hat{S}_x = (\hat{a} + \hat{a}^\dagger + \hat{b} + \hat{b}^\dagger)/2\sqrt{2}$ or $\hat{S}_y = -i(\hat{a} - \hat{a}^\dagger + \hat{b} - \hat{b}^\dagger)/2\sqrt{2}$ is reduced below the symmetric limit. From the viewpoint of entanglement, the two-mode squeezed state is an entangled state of sublattice magnons. The strength of the entanglement is quantified by log negativity as $E_N = 2|\theta|$ (Yuan et al., 2020b). Note that we focus on the uniform precession mode $k = 0$. The ground-state entanglement of magnons taking into account the magnons with finite wavevectors is found in Hartmann et al. (2021) and the influence of magnon relaxation and dephasing on the entanglement of magnons can be found in Yuan et al. (2022b).

Magnon BEC and spin superfluidity

In addition to the quantum states that were discussed in the previous subsections and that involve one or a few magnons, there also exist interesting quantum many-body states of magnons. Most prominent among these is magnon BEC. A magnon BEC may exist in equilibrium or out of equilibrium (Zapf et al., 2014). In the former case, the spin system has a uniaxial symmetry which is spontaneously broken. The simplest example is that of an easy-plane magnet. For large external fields perpendicular to the easy plane, the spins are fully polarized in the direction of the field. Upon reducing the field, the magnetization tilts away from the field direction for a critical field that is of the order of the easy-plane anisotropy. As the projection of the magnetization on the easy plane is undetermined, this transition spontaneously breaks the rotation symmetry around the field direction. The transition is of second order and may be interpreted as magnon BEC for HP magnons with the quantization axis in the direction of the field. This is because in the symmetry-broken phase we have that $\langle \hat{S}_x \rangle \neq 0$ and $\langle \hat{S}_y \rangle \neq 0$, and therefore that $\langle \hat{a}_i \rangle \neq 0$. The latter order parameter signals BEC. Nonequilibrium BEC may be achieved when injecting magnons, for example, due to an increase of the temperature (Schneider et al., 2020), and if their equilibration is faster than their relaxation.

A magnon BEC, or, more generally, an easy-plane magnet in the symmetry broken phase, may exhibit spin superfluidity (Sonin, 2010). For the case of the easy-plane magnet, the spin supercurrent is expressed as the gradient of the angle that the magnetization makes in the easy plane. In-plane anisotropies that pin the magnetization within the easy plane lead to a lower critical current for superfluid spin transport. For spin currents larger than an upper critical current, the magnetization tilts out of the easy plane. Recently, the first experimental signals of spin superfluidity were reported (Yuan et al., 2018).

Hybrid magnonic platforms

Magnon–photon system

The history of coupling magnets to electromagnetic waves can be dated back to the 1960s (Auld, 1963; Chow and Hines, 1966). In the early times, one put a magnet into a microwave cavity and observed the anticrossing spectrum when the frequency of the magnetic resonance mode matched that of the cavity field. The gap of the anticrossing characterizes the coupling strength between magnon and photon, and it is determined by the overlap of the spin-wave mode and microwave mode inside the magnet. After half century of dormancy, Soykal and Flatté revisited this topic in 2010 (Soykal and Flatté, 2010) using a quantum mechanical formalism and theoretically predicted that the coupling strength can reach the strong coupling regime by putting an insulating

magnetic sphere into a high-quality cavity. Three years later, Huebl et al. (2013) experimentally verified this prediction by loading gallium-doped yttrium iron garnet (YIG) into a superconducting microwave resonator. Later, Harder et al. (2018) observed energy-level attraction by delicately tuning the position of a YIG sphere in an open Fabry–Perot cavity. It has become clear that the energy-level repulsion and attraction correspond to the coherent and dissipative coupling between magnets and microwaves, respectively. In these studies, a quantum model based on the quantization of magnetic excitations and cavity electromagnetic waves provides a convenient way to understand the coupling spectrum. However, it is not sufficient to claim quantum aspects of the physics. Indeed, most of the physics can also be well understood by employing a coupled oscillator model (Yu et al., 2019; Zare Rameshti et al., 2022). How to manifest quantum correlations of magnons and photons has attracted significant attention recently.

Yuan et al. (2020a) considered the dissipative coupling between magnons and photons described by the non-Hermitian Hamiltonian

$$\hat{H} = \omega_r \hat{a}^\dagger \hat{a} + \omega_c \hat{c}^\dagger \hat{c} + g \left(\hat{c}^\dagger \hat{a} + e^{i\Phi} \hat{c} \hat{a}^\dagger \right), \quad (14)$$

where $\hat{a}$ ($\hat{a}^\dagger$) and $\hat{c}$ ($\hat{c}^\dagger$) are annihilation (creation) operators of magnons and photons, respectively, ω_r (ω_c) is the magnon (photon) frequency, g is the effective coupling strength between magnons and photons, and Φ is a tunable phase factor due to backaction effects. This effective Hamiltonian (14) describes the energy-level repulsion and attraction observed in experiments very well (Bhoi et al., 2019; Boventer et al., 2020; Harder et al., 2018).

Fig. 4A shows the typical spectrum of energy-level attraction with $\Phi = \pi$. By solving the quantum master equation corresponding to the Hamiltonian (14), it is found that the hybrid system evolves to a steady state with maximum entanglement $\ln 2$ in the regime of energy level attraction as illustrated in Fig. 4B. Detailed analysis shows that the steady state is a Bell state between magnon and photon, that is, $|\phi_s\rangle = (|10\rangle + |01\rangle)/\sqrt{2}$. Such entanglement is robust as long as the coupling strength is larger than the magnetic dissipation as shown in Fig. 4C. For comparison, the system keeps oscillating and no steady Bell states are generated outside the regime of level attraction.

Another way to generate entanglement between magnons and photons is to utilize the nonlinearities in magnetic systems. Li et al. (2018) studied a hybrid magnon-photon-phonon system by further including the pressure-like interaction between magnons and phonons, as $\hat{a}^\dagger \hat{a} \hat{q}$ with $\hat{q}$ being the position operator of phonons (see more details below). By driving the magnetic mode, an effective squeezing interaction between magnons and phonons is produced and contributes to both bipartite and tripartite entanglement among magnons, photons, and phonons.

Magnon-qubit system

A qubit is a quantum-mechanical two-level system that can store binary information and is the basic element for quantum computing and information processing. Quite a few types of qubits have been realized to implement quantum information tasks, such as superconducting qubits, photonic qubits, and nitrogen-vacancy (NV) centers. On the one hand, the single-spin

(B) Evolution of the entanglement and the fidelity of the temporal state to the Bell state as a function of time. (C) Robustness of the steady Bell state against dissipation with different coupling strengths between magnons and photons (g). Adapted from Yuan HY, Yan P, Zheng S, He QY, Xia K, and Yung M-H (2020a) Steady bell state generation via magnon-photon coupling. Physical Review Letters 124(5): 053602. <https://doi.org/10.1103/PhysRevLett.124.053602>.

qubit, for example the NV center, can be used to detect magnetic states including magnetic domains, domain walls, and skyrmions, while a magnetic structure can mediate the entanglement of two and more spin qubits. On the other hand, a superconducting qubit can be coupled with the magnon mode via cavity photons and achieve mutual information transfer between magnonic system and qubit system. In this section, we will focus on these two aspects.

Trifunovic et al. (2013) first proposed to couple two spin qubits separated by a distance of several μm through magnon excitations in a ferromagnet, as shown in Fig. 5A. Here the two qubits are coupled to the ferromagnet through dipolar interactions. Therefore, the qubit has to be placed close to the magnets, that is, on the order of several tens of nanometers, to guarantee that the coupling strength is sufficiently strong. The on-and-off switching of the qubit–qubit interaction can be realized by adjusting the detuning between the qubits and the ferromagnetic resonance mode. Note that the decoherence time of the qubit T_2 depends sensitively on $k_B T / \Delta_F$, where Δ_F is the magnon gap, which suggests that it is desirable to choose magnetic materials with a small magnon gap and to perform the quantum operations at cryogenic conditions. Neuman et al. (2020) showed that a nanomagnet can mediate the long-range coupling of two qubits as shown in Fig. 5B. By tuning the frequency of the magnon to be off-resonant with the qubit, each qubit is coupled to the magnon mode inside the nanomagnet through the transfer of virtual magnons. They found population exchange between the two qubits, which clearly demonstrates the indirect coupling between them. The effective coupling strength is three to four orders of magnitude larger than the direct coupling strength. Furthermore, the generation of two-qubit entangled states via dissipative coupling between qubit and a magnetic medium (Zou et al., 2021) and preparation of 3-qubit Greenberger–Horne–Zeilinger (GHZ) states through the emission of a squeezed magnon (Skogvoll et al., 2021) are also proposed in literature.

Fig. 5 (A) Schematic of a ferromagnetic coupler where the orange dog-bone shape denotes the ferromagnet that is coupled via dipolar interaction to spins of nearby spin qubits (purple spheres with green arrows). (B) Schematic of two qubits coupled by a magnon mode in a nanometer-sized magnetic sphere. The bottom-left panel shows the population of the two qubits as a function of time and bottom-right panel shows the effective coupling strength of two qubits mediated by magnons with and without magnets. (C) Schematic of the coupling of two qubits via the magnon mode in an AFM insulator. Here QI is the abbreviation of quantum impurity. Adapted from Flebus B and Tserkovnyak Y (2019) Entangling distant spin qubits via a magnetic domain wall. *Physical Review B* 99(14): 140403. <https://doi.org/10.1103/PhysRevB.99.140403>; Neuman T, Wang DS, and Narang P (2020) Nanomagnonic cavities for strong spin-magnon coupling and magnon-mediated spin-spin interactions. *Physical Review Letters* 125(24): 247702. <https://doi.org/10.1103/Phys-RevLett.125.247702>; Trifunovic L, Pedrocchi FL, and Loss D (2013) Long-distance entanglement of spin qubits via ferromagnet. *Physical Review X* 3(4): 041023. <https://doi.org/10.1103/PhysRevX.3.041023>.

Besides utilizing magnons excited in a collinear magnetic structure as illustrated above, Flebus and Tserkovnyak (2019) theoretically showed that an AFM domain wall is able to mediate a tunable coherent coupling between two qubits separated by a micrometer as shown in Fig. 5C. Here the planar rotation of the staggered order parameter, that is, the spin superfluid mode, is excited and simultaneously coupled to two qubits placed above the magnetic texture. We note that the experimentalists have realized the coupling between one spin qubit and a magnet (Andrich et al., 2017; Candido et al., 2020; Kikuchi et al., 2017; Wolf et al., 2016), while the demonstration of qubit–qubit entanglement through magnon modes is still lacking.

To study the coupling between magnon and superconducting qubit, Tabuchi et al. (2015) first considered a hybrid magnetic-qubit-cavity system composed of a YIG sphere and a superconducting transmon qubit, as illustrated in Fig. 6A. Here the magnons and photons are respectively coupled to the magnetic and electric components of the cavity field, and hence there is a bridge between magnons and qubits by exchanging a virtual photon, that is $\mathcal{H}_{\text{int}} = g_{\text{mq}} \hat{\sigma}^+ \hat{a} + g_{\text{mq}}^* \hat{\sigma}^- \hat{a}^\dagger$, where $\hat{\sigma}^\pm$ are the Pauli rising and lowering operators describing the state of a qubit. Here the effective coupling strength g_{mq} depends on the respective coupling and detuning between photons and magnons (qubits). To quantify the coupling, the authors probed the qubit state by another cavity mode and identified a typical energy-level repulsion spectrum with a gap of 10 MHz, as shown in Fig. 6B. This coupling strength is much larger than the dissipation of qubits and photons and thus it falls into the strong coupling regime. Based on the strong coupling, in a follow-up work, Lachance-Quirion et al. tuned the system into a strongly dispersive regime, where the detuning between magnon and qubit is much larger than their effective coupling. This generates a nonlinear interaction between magnon and

qubit in the form of $\hat{\mathcal{H}}_{\text{int}} = \chi_{\text{qm}} \hat{a}^\dagger \hat{a} \hat{\sigma}_z$ (Lachance-Quirion et al., 2017, 2020), which means that the excitation of magnons will induce a frequency shift of the qubit. Since the qubit occupation can be measured by cavity field, this provides a way to detect magnon excitations through the read-out of the qubit state. To demonstrate this idea, the authors first prepared a coherent state of magnons and then applied a conditional excitation X_π^0 pulse on the qubit to entangle the magnons and qubit, as shown in Fig. 6C. By reading the qubit through a high-power technique, the magnon excitation down to the single magnon level is detected with high precision as illustrated in Fig. 6D. This proof-of-concept experiment establishes the qubit state as single-magnon detector, which has promising applications to detect weak magnon excitations with high precision.

Magnon–phonon system

The coupling between magnons and phonons is another interesting direction. Here a phonon mode may be either the quantization of a lattice deformation of a magnet or that of a distant mechanical oscillator. While traditional spintronics mainly focuses on the excitation and transport properties of magnons mediated by phonons (Bozhko et al., 2020), quantum magnonics concerns the entanglement between magnons and phonons as well as the application of hybrid magnon-phonon systems in quantum information science.

In general, the magnetization oscillation of a magnet can induce mechanical deformations of the lattice through the magnetostrictive interaction in the form of (Rückriegel et al., 2014)

$$\hat{\mathcal{H}}_{\text{int}} = b_1 \int_V d^3r \left[\hat{m}_x^2 \varepsilon_{xx} + \hat{m}_y^2 \varepsilon_{yy} - (\hat{m}_x^2 + \hat{m}_y^2) \varepsilon_{zz} \right], \quad (15)$$

where b_1 is a magnetoelastic constant, $\varepsilon_{ij} \equiv (\partial_i u_j + \partial_j u_i)/2$ are the components of the strain tensor, $\mathbf{u}$ is the atomic displacement, and V is the volume of the magnet. By properly choosing the direction of magnetization, the interaction between magnons and phonons can be quantized as (Zhang et al., 2016)

$$\hat{\mathcal{H}}_{\text{int}} = \frac{b_1 M_s}{V} \hat{a}^\dagger \hat{a} \int d^3r (\varepsilon_{xx} + \varepsilon_{yy} - 2\varepsilon_{zz}) = g_{\text{mb}} \hat{a}^\dagger \hat{a} (\hat{b} + \hat{b}^\dagger), \quad (16)$$

where $\hat{b}$ ($\hat{b}^\dagger$) is the annihilation (creation) operator for phonons, M_s is saturation magnetization, and g_{mb} is the effective coupling strength.

Zhang et al. (2016) first studied a hybrid cavity-magnet system by taking the phonon degree of freedom into account, as shown in Fig. 7A. They tuned the magnon frequency close to the photon frequency to realize hybrid modes of the magnons and photons ($\hat{A}_\pm$) with their frequency in the gigahertz regime, as illustrated in Fig. 7B. To match the phonon frequency in the megahertz regime, a parametric driving is applied on the cavity field such that the detuning between cavity photon and the driving will be comparable to that of phonons and the phonon mode will be effectively excited. In the dressed basis, the interacting component of Hamiltonian becomes $\hat{\mathcal{H}}_{\text{int}} = g_{\text{mb}} (\hat{b} + \hat{b}^\dagger) (\sin^2 \theta \hat{A}_+^\dagger \hat{A}_+ + \cos^2 \theta \hat{A}_-^\dagger \hat{A}_-)$, where θ is a tunable parameter that depends on the coupling strength and detuning between magnons and photons. This interaction contains both beam-splitter-type interaction ($\hat{A}_\pm^\dagger \hat{b} + \hat{A}_\pm \hat{b}^\dagger$) and parametric interaction ($\hat{A}_\pm^\dagger \hat{b}^\dagger + \hat{A}_\pm \hat{b}$) between the dressed mode and the phonon mode. Thanks to the tunability of magnon frequency, the relative contribution of these two types of interaction is also tunable, which enables the observation of transmission phenomena in the hybrid system, for example the magnon analog of electromagnetically induced transparency and absorption.

Based on this platform, Li et al. (2018) studied the existence of steady entanglement among magnons, photons, and phonons induced by the nonlinear interaction between magnons and phonons. Sarma et al. (2021) proposed a way to transfer the information from cavity mode to phonon mode. Due to the low damping rate of the phonon mode, the information encoded in the phononic subsystem may survive for a longer time and thus may be used as memory. Alternatively, Colombano et al. (2020) experimentally realized a hybrid magnet-mechanical system by depositing a glass of microsphere optical cavity on top of a YIG thin film. The oscillating field acting on the magnetic sphere deforms the magnetic lattice and further excites the breathing mode of the microsphere through magnetostrictive interactions. By measuring the state of the microsphere, the oscillating field can be indirectly recovered. This technique can thus be used as a magnetometer with high sensitivity in the megahertz regime.

Conclusion

In conclusion, we have briefly introduced the nascent field of quantum magnonics and discussed the recent developments concerning hybrid magnonic systems as well as their applications to quantum memories, logic gates, and high-precision sensors. Despite great success, the progress of this field is far from satisfactory. Most of the magnon quantum states including magnon antibunching, squeezed states, and cat states, are yet to be verified in experiments. There are already many proposals on how to generate these states; however, the readout as well as the applications of these quantum states have to be further developed. A key question we may have to keep asking ourselves is how magnonic systems could stand out among other quantum platforms, including superconducting qubits, single-spin qubits, and cavity photons to realize quantum information processing. The answer to this question may be crucial for the long-term development of this field.

Abstract

Progress in spintronics has been achieved with novel device concepts and the subsequent development of optimized materials and heterostructures to implement them. The heterostructures typically combine magnetic and nonmagnetic elements, which enable the integration of non-volatile magnetic memories and sensors in electrical circuits. This chapter provides an overview of spintronic devices that have found industrial applications with a focus on the materials and heterostructures being used. It further discusses selected material families that can potentially enhance device performance and/or create new application opportunities, including transition metals, magnetic insulators, antiferromagnets, altermagnets, Heusler compounds and van der Waals materials.

Key points

- Introduction to spintronics devices, magnetic memories and sensors
- Historical overview on spintronic concepts and material development
- Description of selected key phenomena and materials
 - Giant magnetoresistance (GMR)
 - Tunnelling magnetoresistance (TMR)
 - Magnetic random-access memory (MRAM)
 - Spin-transfer torque (STT)-MRAM
 - Spin-orbit torque (SOT)-MRAM
 - Voltage control of the magnetization (VCMA)
 - Magnonics
 - Transition metals
 - Heusler compounds
 - 2D van der Waals materials
 - Antiferromagnets and altermagnets
 - Magnetic insulators
- Future directions

Abbreviation

AFM	antiferromagnet
AMR	anisotropic magnetoresistance
BEOL, FEOL	back-end-of-line, front-end-of-line
BP	black phosphorous
CIP	current in plane
CMOS	complementary metal-oxide semiconductor
CPP	current-perpendicular-to-plane
DW	Domain wall
FL	free layer
GMR	giant magnetoresistance
HC	Heusler compound
ISGE	inverse spin galvanic effect
IP	in-plane
MTJ	magnetic tunnel junction
MRAM	magnetoresistive random access memory
PMA	perpendicular magnetic anisotropy
OOP	out of plane
RA	resistance-area
REE	Rashba-Edelstein effect
RL	reference layer
SAF	synthetic antiferromagnet
SHE	spin Hall effect
SMR	spin Hall magnetoresistance
SOI	spin-orbit interaction
SOT	spin-orbit torque
SRAM	static random-access memory
STT	spin transfer torque
SW	spin wave
TMDC	transition metal dichalcogenide
TMR	tunnel magnetoresistance
TI	topological insulator
USMR	unidirectional spin Hall magnetoresistance
VCMA	voltage control of magnetic anisotropy
vdW	van der Waals
YIG	yttrium iron garnet

Introduction

Spintronics utilizes the electron spin degree of freedom to store and manipulate information, typically relying on material heterostructures that include magnetic and nonmagnetic elements. The interconversion of electrical and spin signals enables the seamless integration of non-volatile magnetic memories and sensors in electrical circuits, which brings substantial benefits in terms of dimensional scaling, power consumption, and data processing speed (Žutić et al., 2004). Recent advances in the understanding of charge-spin interconversion phenomena and the optimization of materials have opened new avenues to incorporate both Boolean and non-Boolean logic functions as well as high-frequency microwave devices in spintronic circuits (Sinova et al., 2015; Manchon et al., 2019; Dieny et al., 2020).

Commercial implementations of spintronic sensors and magnetic random-access memories (MRAMs) are based on the anisotropic, giant or tunnelling magnetoresistance effects (Apalkov et al., 2016; Zheng et al., 2019; Dieny et al., 2020; Khan et al., 2021). Magnetic sensors are used in automotive, consumer electronics, healthcare, and industrial applications (Zheng et al., 2019). They can detect small changes in magnetic field strength or in the orientation and position of a magnet, making them well suited for applications in hard disk drives, navigation, positioning, speed measurements and tracking. The anisotropic magnetoresistance (AMR) refers to the change in electrical resistance of a ferromagnetic material when its magnetization is rotated relative to the current direction. AMR sensors are easy to integrate, relatively small and have a low-cost compared to other magnetic sensing technologies. Giant magnetoresistance (GMR) and tunnel magnetoresistance (TMR) sensors offer higher sensitivity and resolution than AMR sensors.

Fig. 1 (a), The basic unit of GMR and TMR devices consists of two ferromagnetic layers (FM) separated by a nonmagnetic (NM) spacer. The NM spacer can be a metal (GMR), or an insulator (TMR) to create a magnetic tunnel junction (MTJ). The magnetization of the free layer (FL) can change direction while that of the reference layer (RL) is pinned. (b), The main mechanisms to change the FL magnetization are (from left to right): the Oersted (or external magnetic) fields, spin-transfer torque (STT), the voltage control of the magnetic anisotropy (VCMA), the spin-orbit-torque (SOT) and domain-wall (DW) motion. Figure adapted from Krizakova V, Perumkunnil M, Couet S, Gambardella P, Garello K, (2022) Spin-orbit torque switching of magnetic tunnel junctions for memory applications. *Journal of Magnetism and Magnetic Materials*, 562, 169692. doi:10.1016/j.jmmm.2022.169692.

The basic unit to observe the GMR and TMR effects is a trilayer FM/NM/FM consisting of two ferromagnetic layers (FM) separated by a nonmagnetic (NM) spacer (Fig. 1). The resistance of the trilayer changes with the relative alignment of the magnetization in the two FM layers. For both sensing and memory applications, the magnetization of one of the two FM layers in the FM/NM/FM stack is pinned and serves as “reference,” whereas the other is “free” to change direction under a magnetic field or a spin-polarized current. The FM layers have a preferential magnetization direction, dictated by the uniaxial magnetic anisotropy, which is induced by either crystalline, shape or interfacial effects. Additionally, a synthetic antiferromagnet (SAF) is deposited above (or below) the reference layer (RL) in order to pin its magnetization. The SAF is composed of a high-coercivity magnetic multilayer stack, which is coupled to the RL through a thin nonmagnetic spacer by the Ruderman-Yosida-Kasuya-Kittel (RKKY) interaction. Alternatively, for in-plane magnetized FM/NM/FM structures, the RL can be pinned by exchange bias to an adjacent antiferromagnetic layer (Nogués and Schuller, 1999). In magnetic memory applications, a logic bit state, 0 or 1, is encoded in the direction of the magnetization of the free layer (FL). The bit state is then read by a magnetoresistance measurement that distinguishes between the parallel (P) and antiparallel (AP) alignment between the magnetizations of the FL and RL. In sensing applications, the magnetization of the FL tilts in response to an external magnetic field, e.g., in proximity of a magnetic object, and the relative angle with the magnetization of the RL is measured by analogue variations of the GMR or TMR effects, depending on the type of device.

State-of-the-art MRAM cells rely on the TMR effect, in which the NM spacer is a thin insulator and the trilayer forms a magnetic tunnel junction (MTJ). Typical MRAM stacks are built by numerous ultrathin layers, each of them with a distinct role in determining the memory performance (Apalkov et al., 2016; Dieny et al., 2020; Yang et al., 2022). The number and purpose of the layers and the design of the MTJ have evolved over the years following several major material and technological breakthroughs aimed at increasing the TMR, lowering the power required to control the FL magnetization, and maintaining thermal stability and data retention when downscaling the MTJs. The spin-transfer torque (STT) effect has emerged as a key technology to switch the FL magnetization using electrically generated spin currents (Chappert et al., 2007; Ralph and Stiles, 2008; Stamps et al., 2014; Apalkov et al., 2016; Sander et al., 2017; Vedmedenko et al., 2020; Na et al., 2021; Brataas et al., 2012) (Fig. 1). The current through the tunnel barrier is spin-polarized, leading to the FL magnetization reversal owing to the transfer of angular momentum. STT-MRAM are commercialized as standalone memories and wearable electronics. They are also considered as the best candidates for embedded non-volatile applications, as replacement of embedded flash and static RAM (SRAM) (see Section “Conventional materials and current applications”).

The figures of merit of GMR and TMR devices depend critically on the composition and thickness of all the magnetic and nonmagnetic layers in the stack, and particularly on their structural quality, including interfacial stoichiometry and roughness. For technological applications, the fact that interfacial effects dominate the GMR and TMR is an advantage, as it helps reduce the devices volume without impairing their performances and the power required to switch them. Minimizing the device size also reduces the self-demagnetizing fields produced by both the RL and the FL. For sensors, this implies a larger sensitivity of the FL to external magnetic fields, while, for memories, this implies smaller interaction between neighboring devices and therefore larger bit density. Reducing the variability of the magnetic and electrical parameters across devices patterned on the same wafer and from wafer to wafer is crucial for applications. This is important for MTJ devices, in which the TMR scales exponentially with the tunnel barrier thickness.

The growing demand for spintronic devices with high-density, high-speed and low-power consumption necessitates advances in terms of materials and device architectures (Dieny et al., 2020). This chapter starts with an historical overview of conventional and

emerging materials used in spintronics. This overview is complemented by an in-depth description of the different materials, concepts and envisioned material advantages and bottlenecks. Requirements for further progress, novel materials that could meet those requirements, and the opportunities that can arise with them are also discussed. These materials include Heusler compounds, 2D van der Waals (vdW) materials, antiferromagnets, altermagnets and magnetic insulators. Fig. 2 highlights some of the main milestones for each of the selected material families.

The chapter ends with a summary of future directions. Given the intense research activity on spintronics, it is not possible to cover the vast literature available in a limited space. As a complement to this chapter, the reader is instead referred to comprehensive reviews, books, roadmaps and perspectives that have been published in recent years.

Historical overview

The development of spintronics started with the discovery of the GMR effect in 1988 (Fert and Van Dau, 2019) (Fig. 2). GMR rapidly found several applications as sensors and in 1996 as read heads in hard disk drives. The discovery of material systems with TMR exceeding 100% at room temperature led to a generational change in the early 2000s and the widespread adoption of MTJs as the basic unit of magnetic storage and sensing (Parkin et al., 2003; Miao et al., 2011; Dieny et al., 2020). Although AMR and GMR effects are still being used for low-cost sensing applications, TMR is ubiquitous in the most advanced device generations. Because the density of states of FM materials are spin-split and tunnelling is a spin conserving process, the TMR depends on the product of the effective spin polarization of the two FM electrodes. This dependence leads to a maximum room temperature TMR ratio of about 70% in amorphous Al_2O_3 barriers sandwiched between transition-metal electrodes such as CoFe, owing to the partial spin polarization of the conduction electrons near the Fermi level. A breakthrough occurred with the introduction of epitaxial junctions

Fig. 2 Spintronic milestones for industrial developments and scientific advances associated to the material families discussed in this chapter.

and crystalline MgO barriers, in which the electron tunnelling probability additionally depends on the symmetry of the wavefunctions penetrating the barrier. Experimentally demonstrated TMR values in CoFeB/MgO/CoFeB junctions exceed 600% at room-temperature (Miao et al., 2011). The largest TMR reported so far has been obtained using $\text{Co}_x\text{Fe}_{80-x}\text{B}_{20}$ electrodes with $x = 20\text{--}40\%$ and 1–2 nm-thick MgO barriers.

No other materials compatible with industrial process requirements have been found to improve the TMR and, in the last decade, applications have evolved around MgO-based MTJs. The crystalline properties and TMR of the structures have steadily improved and suitable SAF multilayers and interfacial perpendicular magnetic anisotropy (PMA) have been developed. However, MgO-based MTJ devices appear to be reaching their limit. As they are made smaller, and the MgO tunnel barrier thinner, several technological challenges are becoming difficult to overcome, including side wall re-deposition, the increasing aspect ratio of etched structures or the relative increase of the MgO insulator roughness.

Besides GMR and TMR, other magnetization readout mechanisms, relying on charge spin interconversion have been proposed. They include the spin Hall magnetoresistance (SMR) and unidirectional spin Hall magnetoresistance (USMR). Their sensitivity is relatively small, and their primary use has been to determine the magnetic state of insulators in fundamental research studies.

Writing in commercialized MRAM has been achieved using a magnetic field, generated by an applied current (implemented in toggle MRAM), and by the previously mentioned STT (Figs. 1 and 2). Interfacial PMA has become crucial because perpendicularly magnetized stacks downscale better than the in-plane magnetized ones (Dieny and Chshiev, 2017). This improves the trade-off between the thermal stability of the FL magnetization and the write current for the switching dynamics induced by STT. However, an enhanced PMA, required when the memory is downscaled, results in increased current densities to achieve magnetization switching, which in turn increase energy consumption and can damage the MTJ.

The voltage control of magnetic anisotropy (VCMA) has been proposed as a solution to assist or directly induce magnetization switching (Dieny and Chshiev, 2017; Miwa et al., 2018; Rana and Otani, 2019; Yamamoto et al., 2022). In addition, the spin-orbit torque (SOT) is an alternative to the STT that uses a charge current flowing in a heavy metal layer to inject a spin-polarized current into the adjacent FL through spin-orbit coupling effects such as the spin-Hall and/or Rashba–Edelstein (inverse spin galvanic) effect (Sinova et al., 2015; Manchon et al., 2019; Krizakova et al., 2022). Unlike STT technology, magnetization reversal by SOT can be achieved without passing a current through the MTJ tunnel barrier (Fig. 1). By decoupling of the write and read current paths, it circumvents write errors during read operation and reduces the risk of dielectric breakdown. Although neither VCMA nor SOT are yet sufficiently strong for implementation in commercial devices, their combination with STT is promising for improving the efficiency, reliability and speed of MRAMs (Krizakova et al., 2022).

Besides the successful magnetic sensors and MRAM, other concepts are under development such as racetrack memories and logic devices using the propagation of magnetic skyrmions or domain walls (DW), driven by either STT or SOT (Atkinson et al., 2006; Parkin and Yang, 2015; Soumyanarayanan et al., 2016; Fert et al., 2017; Hrabec et al., 2020; Dieny et al., 2020). Spintronics is also being investigated for wireless communication applications. Spin torques in nanoscale MTJs can lead not only to magnetization switching but also to self-sustained oscillations of the FL magnetization, which can be used for dc to radiofrequency (RF) conversion in microwave signal generators; the reciprocal effect can be used for microwave signal detection (Demidov et al., 2017). STT-nano-oscillators have also been investigated in neuromorphic computing architectures (Christensen et al., 2022) while THz emission has been achieved in magnetic multilayers (Vedmedenko et al., 2020). Magnonics, which has attracted significant attention in recent years, is a different approach to spin logic that encodes information in the amplitude or phase of spin waves (SW) in magnetic metals or insulators (Stamps et al., 2014; Sander et al., 2017; Brataas et al., 2020; Barman et al., 2021; Pirro et al., 2021; Chumak et al., 2022).

Regarding material processing, new protocols are required for improving the downscaling of devices (for example to avoid sidewall redeposition). Other proposals target novel families of materials while device concepts and applications are continuously put forward, which could benefit from material development. Heusler materials is one such family (Dieny et al., 2020; Hirohata and Lloyd, 2022) (Fig. 2). They comprise a vast catalogue of compounds with high degree of flexibility and physical properties, ranging from semiconductors with tuneable bandgap, superconductors, half-metallic FMs, compensated antiferromagnets, and even topological insulators. Alloys based on Heusler compounds (HC) are promising materials for spintronic applications due to their high saturation magnetization and Curie temperatures, and predicted half-metallic ferromagnetism, i.e., they exhibit metallic behavior for one spin channel and present a gap at the Fermi level for the other. Large GMR and TMR effects have been demonstrated with HCs. However, these materials tend not to perform well at high temperatures and processing with industrial compatible methods is in development.

The atomically thin nature of 2D materials offers significant opportunities (Han et al., 2014; Avsar et al., 2020; Sierra et al., 2021; Yang et al., 2022). It promotes the creation of artificial quantum materials in the form of van der Waals (vdW) heterostructures, where the 2D crystals attach to each other via weak vdW interactions. This represents a new paradigm in material design that is particularly attractive for spintronic devices, which typically harness their functionalities out of thin layers of magnetic and non-magnetic materials and the interfaces between them. Given the ever-growing number of 2D materials available, it might be plausible to replace their 3D counterparts, one by one, whenever the desired functionalities are identified (Fig. 2). VdW heterostructures have the potential advantage of atomically smooth interfaces and reduced thicknesses, eventually down to the monolayer limit, which are both required for downscaling. They would also allow engineers to seamlessly integrate multiple functionalities because the stacking of 2D materials is expected to be less restrictive regarding (crystalline) matching between the involved layers. The 2D material functionalities could go beyond applications in conventional MRAM and sensors and include opto-spintronics, antiferromagnetic spintronics and magnonics. However, the main challenges of any electronic technology based on 2D materials

are upscaling and integration. 2D materials currently suffer from reproducibility and a lack of industrially compatible growth and device fabrication processes (Sander et al., 2017; Och et al., 2021; Yang et al., 2022).

Another highly influential research field in the last decade is the control and manipulation of magnetically ordered materials with zero net magnetization, such as antiferromagnets (Jungwirth et al., 2016; Baltz et al., 2018) and the recently coined altermagnets (Šmejkal et al., 2022b). The aim is to exploit the advantages that come from an absence of stray magnetic fields and a natural excitation at high frequencies, in the THz regime (Gomonay et al., 2018). The compensated magnetic order results in an insensitivity to external magnetic fields and the possibility for optimal space downscaling of memory devices due to the absence of demagnetizing fields. At the same time, the high resonant frequencies, due to the exchange enhancement effect that couples the different spin sublattices, makes these materials natural candidates for optical manipulation devices that bridge the THz communication gap (Fig. 2). The main challenges are the need to develop efficient read-out and control methods of the material magnetic state.

Conventional devices rely on the delocalized electrons present in conducting materials to carry the spin information, which induces losses by Joule heating. However, electrically insulating magnetic materials also enable the spin information to flow between localized magnetic moments via propagating SWs, which transmit information from an atomic site to the other without any Joule dissipation (Fig. 2) (Barman et al., 2021). This offers insulating materials an advantage and several research directions attempt to capitalize on it to achieve technical improvements for manipulating and transmitting information, including non-Boolean, parallel, and neuromorphic computing (Brataas et al., 2020). As in some of the other new materials discussed in this chapter, compatibility with current industrial processes and scalability are arguably the main challenges that need to be resolved.

Key materials: Issues and research directions

Conventional materials and current applications

Giant magnetoresistance (GMR)

The GMR originates from the spin-dependent conductivity of electrons in FM transition metals (Fe, Co, Ni and their alloys) and at FM/NM interfaces (Parkin, 1995). Exchange-biased GMR structures, also called spin valves, are entirely made of metals, typically several repetitions of Co/Cu/Co or Fe/Cr/Fe trilayers coupled to a metallic antiferromagnet with high Néel temperature such as IrMn or FeMn. The best NM spacers are metals with a long electron mean free path, such as Cu, Ag, and Au, and only 1–2 nm-thick in order to minimize current shunting and scattering of the spin-polarized electrons transmitted and reflected between the FM layers (Bass and Pratt, 2007). In the current-in-plane (CIP) geometry, the thickness of the FM layers must be smaller than the largest of the mean free paths of the majority and minority spin electrons in order for the current density in one FM layer to be affected by the magnetization of the next FM layer. Because interfacial spin-dependent scattering often dominates over bulk spin-dependent scattering, the optimal FM thickness is around 1–5 nm. The CIP-GMR is further decreased if the current flows in the nonmagnetic seed layers and capping layers used to promote growth and for protection, respectively. In the current-perpendicular-to-plane (CPP) geometry, in contrast, the electrons necessarily flow through the entire multilayer structure and the magnetoresistance is less affected by the mean free paths of the FM layers. In either geometry, the GMR increases when electrons propagate across many FM/NM interfaces. The largest GMR ratios, defined as $(R_{AP} - R_P)/R_P$, where $R_{AP(P)}$ is the resistance of the AP (P) state, are indeed found in structures with tens of repetitions of the thinnest possible FM and NM layers, and reach up to 65% in $[\text{Co}(0.8 \text{ nm})/\text{Cu}(0.8 \text{ nm})]_{60}$ multilayers at room temperature. Spin-valve devices, however, typically have lower GMR ratios of 25% or less (Parkin et al., 2003).

Tunnel magnetoresistance (TMR)

The highest TMR has been reported in Fe and CoFe grown epitaxially with body-centered cubic (bcc) structure matching the MgO crystal lattice. However, industrial MTJs are obtained by depositing amorphous CoFeB and textured MgO(001) layers using magnetron sputtering, followed by thermal annealing between 300 °C and 400 °C (Miao et al., 2011). This process minimizes the formation of defects in the barrier owing to the growth of high-quality MgO on atomically smooth CoFeB. It also leads to thermally-induced recrystallization of the electrode interfaces and diffusion of B away from the crystallized CoFe layers, which in turn provides the local epitaxial order between the bcc CoFe and MgO (001) lattices that is required for symmetry filtering of the tunnelling electrons. The deposition of B-getter layers next to the FM layers, such as Ta, W, and Hf, further improves the crystallization process and TMR, provided that the getter elements do not diffuse toward the MgO barrier upon annealing, degrading both the crystalline quality of the FM and the barrier itself. In principle, half-metal electrodes with only one spin sub-band crossing the Fermi level, such as $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$, CrO_2 , and some Heusler alloys (see Section “Heusler compounds (HC)”), can achieve significantly higher TMR values than CoFeB. However, these materials do not perform well at high temperature because magnon and phonon excitations impair their half-metallic character.

Other useful properties that make the CoFeB/MgO/CoFeB system the basis of most MTJ designs are the resilience to thermal annealing required for compatibility with back-end-of-line (BEOL) complementary metal-oxide-semiconductor (CMOS) processes and the possibility to fabricate MTJs with FM layers magnetized in-plane or out-of-plane. Whereas in-plane magnetization is easily obtained using CoFeB layers with thickness above 2–3 nm owing to shape anisotropy, out-of-plane magnetized CoFeB are thinner and deposited next to a heavy metal such as Ta or W to improve the interfacial PMA. The interface between the magnetic metals and the oxide promotes PMA due to hybridization effects between the *d*-orbitals of Co and Fe and the *2p* orbitals of oxygen (Dieny and Chshiev, 2017). The magnetic anisotropy barrier of the FL is usually expressed in terms of a uniaxial anisotropy energy constant

$K = 0.8\text{--}1.6 \times 10^6 \text{ J/m}^3$ times the magnetic volume V , which determine the thermal stability factor $\Delta = KV/k_B T$. Although $\Delta \geq 40$ is required to ensure data retention over 10 years at room temperature, it is commonly assumed that $\Delta \geq 70$ is necessary to maintain information at operating temperatures, reaching up 150 °C for certain applications. MTJs based on FM layers with PMA, also called perpendicular MTJs, have better stability factors compared to in-plane MTJs of equal size, and lower stray fields, which are important properties for good readability, size reduction, and densification. On the other hand, MTJs with large Δ require larger fields or currents for switching the FL magnetization. Typical TMR reported in MTJs for MRAM applications are about 180% for perpendicular MTJs, and 250% for in-plane MTJs. This is mostly due to the thicker magnetic layers that can be used in in-plane MTJs, which improve the spin polarization of the tunnelling electrons. A further increase of Δ in perpendicular MTJs can be obtained by adopting a dual-FL/MgO structure, in which an extra MgO/CoFeB interface enhances the PMA (Dieny and Chshiev, 2017).

The RL is coupled to a hard SAF multilayer, typically $[\text{Co/Pt}]_N/\text{Ru}/[\text{Co/Pt}]_M$, by a thin nonmagnetic metal layer such as Ru, W or Ta in order to pin its magnetization. This metal insertion is equally important to decouple the SAF layer texture, usually (111), from the (100) CoFe texture. The SAF is used also to minimize the stray field from the RL, which is crucial to ensure symmetric switching current of the FL. In general, extensive stack engineering and optimization are required to optimize the TMR and Δ while remaining compatible with the BEOL CMOS thermal budget. The device resistance is determined by the tunnel barrier thickness, which is characterized by the resistance-area-product (RA). The optimal RA is strongly dependent on the application domain and dimensions of the device. It is tuned accordingly to the reading speed requirements, i.e., impedance matching, and the minimum current that can be detected by the peripheral electronics. The RA targets are 3–5 $\Omega\cdot\mu\text{m}^2$ (5–10 k Ω) for STT-MRAMs, $\sim 0.5 \Omega\cdot\mu\text{m}^2$ for hard drive read heads, and $\sim 1000 \Omega\cdot\mu\text{m}^2$ for large area sensors. Decreasing the RA below 10 $\Omega\cdot\mu\text{m}^2$ is relevant for further miniaturization of the MRAM bit cells, but usually involves a decrease of the TMR.

STT-MRAM

The STT strength is proportional to the spin polarization and amplitude of the tunnelling current, which makes it naturally compatible with the materials and processes used to optimize the TMR in MTJ devices (Dieny and Prejbeanu, 2017). STT allows for using two-terminal MTJs with shared reading and writing paths (Fig. 1), leading to a compact design of the MRAM bit cells scalable to $4\text{--}6F^2$, where F is the half distance between adjacent cells. The critical STT switching current is proportional to the magnetic damping parameter, magnetic volume, and magnetic anisotropy of the FL, and thus downscales favorably with the area of the MTJ. The RA product of the MgO tunnel barrier and the critical current determine the size and voltage of the transistor used to selectively switch the MTJ. Typical RA and critical currents density for STT-MRAMs are in the range of 3–5 $\Omega\cdot\mu\text{m}^2$ and 3–5 MA.cm $^{-2}$, respectively.

The first step of the STT-MRAM manufacturing process is the front-end-of-line (FEOL) fabrication of transistors on the semiconductor wafer followed by metallic layers (lines and via) routing their electrical contacts to a bottom electrode contact for the MTJ. The BEOL process consists of magnetic stack deposition, photolithography, etching, dielectric isolation, metal contacts and passivation (Gaidis, 2017). A chemical-mechanical polishing step is required to smooth the substrate prior to each integration module and is critical for the deposition of the magnetic stack. The root mean square substrate roughness should be of the order of 0.1 nm in order to obtain high TMR values, large breakdown voltage, and tight distribution of the electrical and magnetic parameters of the MTJs. Rough MgO interfaces should be avoided as they lead to magnetostatic coupling of the free and reference layer and pinhole formation through the barrier. The process temperature should remain below 400 °C in order to minimize interface diffusion between the different layers in the stack while remaining BEOL compatible. Subtractive patterning by ion beam etching or reactive ion etching is used to define the MTJ pillars, which requires a metallic hard mask (usually TiN) to withstand the etchants used for the magnetic materials. The hard mask also provides a self-aligned top contact to the MTJ device.

High-performance STT-MTJ cells are included in the first MRAMs that have been commercialized as replacement for embedded flash memory. Additionally, owing to their scalability, reduced write energy per bit, low leakage, high-speed and endurance, STT-MRAMs represent one of the most appealing non-volatile RAM technologies available for last-level cache memory replacement for internet of things (IoT) applications, always-on processors, and edge artificial-intelligence (AI) computing. Challenges for the further deployment of STT-MRAMs are of two types. First, the fabrication of dense STT-MRAMs arrays below the 14-nm technology node is hindered by the etching of magnetic films, which leads to by-products that cause sidewall redeposition, corrosion, and electrical short of the MTJ. Proposed solutions include combining reactive ion etching and ion beam etching as well as decreasing the thickness of the hard mask to reduce shadowing effects. Second, the shared reading/writing path increases the susceptibility to erroneous writing, read disturbance, and tunnel barrier degradation. These effects become prominent at high operation frequencies, which effectively limits the writing latency to $>10\text{--}20$ ns. The inherent stochastic character of STT switching also affects the writing latency for low amplitude and duration of the current pulses. The speed and endurance limits of STT-MRAMs can be significantly extended by combining STT with other writing approaches, such as SOT switching and VCMA, which promote deterministic reversal of the FL and do not require passing a strong electrical current through the MTJ barrier.

SOT-MRAM

SOT-MRAM exploits the same CoFeB/MgO/CoFeB/SAF basic structure of STT-MTJs, which makes them compatible with most of the BEOL processes developed for STT-MRAMs. The distinguishing feature is the implementation of the SOT current line as a two-terminal bottom electrode (Fig. 1). The main advantage of SOT-MRAMs is the combination of high switching speed and endurance, which allows for quasi-deterministic reversal of the FL on a 100 ps timescale with sub-ns stochastic distribution of the switching times in perpendicular MTJs. Moreover, because the switching current does not flow through the tunnel barrier, its thickness and RA can be tuned for best reading efficiency and speed without affecting the writing process.

SOTs are a manifestation of the relativistic spin-orbit interaction (SOI) that couples the orbital electron motion to the electron's spin. On the microscopic level, their origin can be explained by different mechanism (Manchon et al., 2019). When a charge current is passed through a nonmagnetic conductor, the SOI mediates its conversion into a transverse spin current that propagates toward the interfaces and where it results in spin accumulation. This mechanism is known as the spin Hall effect (SHE) and is prominent in heavy metals (Sinova et al., 2015). In the presence of broken inversion symmetry, e.g., at the conductor's interface, electrons additionally experience an electric field perpendicular to the interface plane, which acts as a magnetic field in the electron's rest frame and results in non-equilibrium spin accumulation at the interface. This mechanism is known as the Rashba-Edelstein effect (REE) or inverse spin galvanic effect (ISGE) and is prominent at the interface of metals having different electronegativity, oxide interfaces, and 2D materials (Manchon et al., 2015; Gambardella and Miron, 2011). The ISGE is also responsible for charge-spin conversion in materials with spin-momentum locked electron states, such as topological insulators and Weyl semimetals (Bihlmayer et al., 2022). A combination of these effects is also possible, in conjunction with additional phenomena due to electron scattering at the interface between magnetic and nonmagnetic conductors and the generation of spin currents within a magnetic material. Recently, orbital analogues of the SHE and ISGE have been proposed as additional mechanisms for the generation of SOT, provided that the SOI converts an orbital current into a spin current inside or outside the magnetic layer (Go et al., 2021). Overall, the multiplicity of effects that can generate the SOT allows for a wide choice of materials and optimization strategies to maximize their strength and efficiency for magnetization switching.

The most studied sources of SOT are the 5d heavy metals Pt, Ta, and W (Manchon et al., 2019). They exhibit torque efficiencies ξ ranging from 0.1 to 0.5, where ξ is the ratio between the spin current effectively converted into a torque and the charge current used to produce the spin current. In addition to ξ , other relevant figures of merit are the resistivity ρ , the spin Hall conductivity $\sigma_{SH} = \xi\rho^{-1}$ and the spin diffusion length λ_s . The first two parameters determine the power density dissipated in the SOT material, while the third determines its thickness. The interfacial spin accumulation decays over a distance of the order of λ_s , which is only a few nm in the 5d metals. This makes it possible to maximize the SOT produced by very thin nonmagnetic layers, thereby reducing the total current required to achieve, e.g., magnetic switching of an adjacent magnet. Alloys or multilayers containing 5d metals, such as AuPt or [Ti/Pt]_N, exhibit larger ξ compared to single-element systems due to enhanced electron scattering and resistivity. Owing to the combination of strong SOI and relatively small resistivity, the spin Hall conductivity in these materials is among the largest measured, reaching up to $10^5 - 10^6 (\Omega m)^{-1}$.

Metallic antiferromagnets such as MnPt and IrMn are also strong SOT sources, which additionally provide exchange bias to the magnetic layer (Manchon et al., 2019). Interface engineering by nitrification or oxidation of the heavy metal, insertion of ultrathin spacer layers, and the use of electrically insulating antiferromagnetic layers can further improve ξ due to enhanced spin transmission and interfacial spin-orbit scattering. Among the 4d metals, Pd presents sizable SOT and enhances PMA. The 3d metals that generate strong orbital currents can also be used as SOT sources, in particular Cr, V and Ti. These materials have similar ξ and resistivity compared to the 5d metals, which makes them attractive for heavy-metal free applications. However, the orbital diffusion length, namely the orbital counterpart of λ_s , is of the order of 10 nm or larger, which requires relatively thick 3d layers to achieve a significant orbital accumulation at the interface with a ferromagnet, and the orbital current must be converted into a spin current in order to exert a torque on the magnetization. This occurs either inside the ferromagnet or in spacer layers with strong SOI, such as few nm-thick rare earth layers, for which ξ of up to 0.25 has been achieved.

Topological insulators (TIs) such as the bismuth chalcogenides Bi₂Se₃, (Bi_{1-x}Sbx)₂Te₃, and BiSb have also drawn significant interest as SOT sources as they exhibit giant values of ξ , typically 1–2 orders of magnitude larger than the 5d metals and allow for room temperature SOT-induced magnetization switching at low current densities. Other materials that can be used to generate SOTs are vdW materials, discussed later, and oxide heterostructures (Trier et al., 2022). For the time being, however, integrating nonconventional materials in devices for mass production remains a challenge.

At the threshold switching current density j_{th} , the power density is $P_{th} = j_{th}^2 \rho \propto \xi^2 \rho_p$, where ρ_p is the effective resistivity of the current channel and FL in parallel. Resistive materials typically have a high ξ . However, if the SOT electrode is too resistive, a significant portion of the current can be shunted into the FL, decreasing the SOT efficiency. Moreover, the selector transistor of each MRAM cell is not only limited in current (depending on the transistor size and associated cell footprint), but also by voltage, which scales as $j_{th}\rho_p$. Therefore, the adoption of high- ξ materials such as TIs in SOT-MTJs should carefully consider the power requirements as well as BEOL-compatibility.

A drawback in SOT-MRAM based on PMA FL magnetizations is the requirement for a symmetry-breaking mechanism to unambiguously set the FL magnetic state and ensure deterministic bipolar operation. Whereas a constant in-plane magnetic field can efficiently lift the final state degeneracy, device integration requires alternative symmetry breaking mechanisms. These include effective magnetic fields produced by an embedded in-plane magnet, exchange bias from an antiferromagnet, and Dzyaloshinskii-Moriya interaction, RKKY coupling to a ferromagnetic layer, or structural symmetry breaking such as tilted anisotropy, thickness, strain and composition gradients. Additionally, the combination of SOT and STT current pulses in 3-terminal MTJs has been shown to induce field-free switching while preserving beneficial SOT characteristics in terms of speed and write error rates (Krizakova et al., 2022).

Voltage-control of magnetic anisotropy (VCMA)

The VCMA refers to the change of the interfacial magnetic anisotropy caused by an electric field applied perpendicularly to the interface of a magnetic layer. This effect is fully compatible with the MTJ structure, in which most of the voltage applied between the top and bottom electrodes falls across the tunnel barrier. Different microscopic phenomena can induce VCMA and can be roughly

divided in two categories (Miwa et al., 2018). Electric-field induced charge accumulation at the interface of a magnetic layer has been shown to modify the electronic filling of d orbitals with different symmetry, leading to a change of the magnetocrystalline anisotropy energy that can be large enough to induce the transition from an out-of-plane to in-plane easy axis. Alternatively, electric-field induced oxygen migration from an oxide dielectric layer to the interface of the magnetic layer can induce redox reactions that also affect the symmetry and filling of the d orbitals in a reversible way. The efficiency of the VCMA process is measured by the coefficient η , namely the change of PMA energy per unit area divided by the applied electric field. The use of reducible oxides or high-ion-mobility gate dielectrics leads to values of η of up to 10^4 fJ/(Vm) in GdO_x/Co layers. The activation time of the redox-induced VCMA, however, is of the order of seconds, and thus too large for memory applications. The electronic VCMA occurs on timescales that are much faster than the magnetization dynamics typically $\eta \leq 10^2$ fJ/(Vm) in CoFeB/MgO layers (Miwa et al., 2018). Both effects are unipolar, i.e., the reduction of magnetic anisotropy is obtained for a given sign of the applied voltage.

The importance of VCMA is that it takes place without significant current flow across the MTJ. It is thus an energy-efficient effect to either assist or induce switching of the FL. The VCMA effect does not break time reversal symmetry and therefore does not discriminate between magnetic states with opposite magnetization. In both STT- and SOT-induced switching, the VCMA can lower the switching energy barrier, leading to a reduction of the critical switching current. In an MTJ, however, the STT and VCMA bias coincide. Because the STT switching polarity depends on the sign of the voltage, the VCMA effect inverts for parallel-to-antiparallel and antiparallel-to-parallel reversal, making it impractical to assist bipolar switching. This issue is elegantly circumvented if VCMA is used to assist SOT switching in voltage-gate-assisted SOT-MRAMs (Krizakova et al., 2022). The application of VCMA not only reduces the critical switching current, but also the switching incubation time (Krizakova et al., 2022), and allows for selectively addressing SOT-MTJs sharing a common SOT electrode. In principle, VCMA alone can also toggle the magnetization between two opposite states, provided that an external magnetic field is applied perpendicular to the easy axis and the duration of the voltage pulses is timed to half the precessional period of the free layer (Miwa et al., 2018). This toggling technique requires, pre-read and read-verify processes, or a double write process, and a careful reduction of the variability in magnetic anisotropy, damping and pulse duration in order to minimize write errors.

Applications that exploit the VCMA effect would greatly benefit from the development of material systems with higher η , higher perpendicular magnetic anisotropy, and lower damping. In order to induce VCMA-switching of a magnetic layer of area A and thermal stability Δ , a value of $\eta = \Delta k_B T / (AE)$ is required, where $E \approx 1$ V/nm is the electric field applied across the dielectric layer. Main memory applications that have thermal stability $\Delta > 70$ thus require $\eta \approx 10^3$ fJ/(Vm) of electronic origin. The most promising effort in this direction involve epitaxial Cr/ultrathin Fe/MgO junctions with in-plane anisotropy and Fe/ultrathin Ir/MgO junctions with perpendicular anisotropy, for which η of up to 370 fJ/(Vm) has been reported (Miwa et al., 2018; Yamamoto et al., 2022). The enhancement of the VCMA in the latter case is attributed to the large spin-orbit coupling and orbital moment of the Ir atoms dispersed in the Fe layer after annealing, which results also in an increase of the perpendicular magnetic anisotropy. Other approaches to improve η involve the introduction of ultrathin oxide layers with high dielectric constant in the MgO tunnelling barrier, such as TiO_x and HfO_2 .

Heusler compounds (HC)

The predicted room temperature half-metallic behavior in HCs providing 100% spin polarization has promoted vast interest in this class of materials for spintronic applications, particularly as spin injector and detector in GMR and TMR devices (Palmström, 2016; Graf et al., 2016; Elphick et al., 2021; Hirohata and Lloyd, 2022). Additionally, the magnetic properties of HC, e.g., their saturation magnetization, can be controlled by atomic substitution of the constituent elements of the alloy, a degree of freedom that is useful for sensing and MRAM technologies, where stray magnetic fields must be minimized. However, half-metallicity, low magnetic damping, and high Curie temperatures require high crystalline order, which is challenging and depends on the lattice matching with substrates and seed layers. This is the case of the predicted half-metal MnNbSb , which has been investigated for MTJs. Although 100% spin polarization was confirmed by polarized positron annihilation and photoemission experiments in bulk MnNbSb , thin films based on co-sputtered or epitaxial growth show much lower values. Spin-polarized tunnelling experiments in epitaxially grown MnNbSb on $\text{Al}_2\text{O}_3/\text{Al}$ yielded a spin polarization of 28%, a value that depends on atomic disorder and lattice distortion (Graf et al., 2016).

Co-based HCs are especially appealing due to their high prospects for magnetoresistive devices, PMA, spin injection into bulk semiconductors and, more recently, into 2D materials such as graphene (Hirohata and Lloyd, 2022). The list of potential candidates is long with many different compounds already tested, e.g., Co_2FeSi , Co_2MnSi , Co_2MnGe , $\text{Co}_2\text{Fe}_{0.5}\text{Mn}_{0.5}\text{Si}$, and $\text{Co}_2\text{FeAl}_{0.5}\text{Si}_{0.5}$. The first family of Heusler-based MTJs structures utilized AlO_x tunnel barrier, yielding room temperature TMR values from 15% for $\text{Co}_2\text{Cr}_{0.6}\text{Fe}_{0.4}\text{Al}$ to 70% for Co_2MnSi (Elphick et al., 2021). Besides atomic order within the HC film, the surface roughness and the interface between HCs and tunnel barriers have a strong influence on the TMR. As a result, the combination of HC magnetic electrodes with epitaxial MgO barriers have significantly improved the device performance. Room temperature TMR values of 217%, 340% and 365% were obtained for $\text{Co}_2\text{MnSi}/\text{MgO}/\text{CoFe}$, $\text{Co}_2\text{FeAl}/\text{MgO}/\text{CoFe}$ and $\text{Co}_2\text{MnSi}/\text{MgO}/\text{Co}_2\text{MnSi}$ epitaxial MTJs, respectively, suggesting a coherent tunnelling process. With partial substitution of Mn with Fe to form $\text{Co}_2\text{Mn}_{0.73}\text{Fe}_{0.27}\text{Si}$, TMR ratios increased to 430% (Elphick et al., 2021).

Co-based HCs have been also incorporated in CPP-GMR devices (Elphick et al., 2021). Room temperature GMR values of 2.5% and 36.5% using Cr and Ag metal spacers have been reported with Co_2MnSi top and bottom electrodes (Graf et al., 2016). The

choice of the metal spacer becomes essential since long λ_s materials with minimal lattice mismatch with the HC electrode are required. Despite the large lattice mismatch, GMR values at room temperature of 8.5% have been obtained using Co_2MnSi layers sandwiched by a Cu metal spacer. Other approaches include full Heusler CPP-GMR devices using Ru_2CuSn spacers with GMR values of 7% at room temperature. All these considerations have led to the choice of Ag as the most optimal metal spacer. Another important aspect of Co-based HCs is the possibility to induce PMA by varying the Co concentration. Memory STT-MRAM cells based on magnetic HCs with PMA and low magnetic damping have been already developed which reflects the potential of HCs in spintronic technologies (Hirohata and Lloyd, 2022).

The approach to use Co-based HCs for spin injection would—in principle—provide highly efficient spin polarization in some spin logics or interconnect realizations (Elphick et al., 2021). Spin injection into semiconductors using HCs is promising due to their good crystal lattice matching with most semiconductors and their high Curie temperature. However, they have failed to fulfil the expectations mostly due to atomic disorder and interdiffusion of magnetic impurities at the interface with the semiconductor spin channel. Spin injection in $\text{CoMnGe}/\text{GaAs}$ heterostructures yielded spin polarization efficiencies of 25%, which is smaller than the 40% efficiency reached in GaAs using Fe as spin injector. Lateral spin devices with Cu channels and Co_2FeSi spin injectors and detectors yielded spin injection efficiencies of 27%, the highest value reported to date in these hybrid devices. In order to enhance the spin injection efficiency, the intercalation of a MgO tunnel barrier between the semiconductor and the magnetic HC has been proposed (Farshchi and Ramsteiner, 2013).

From a practical point of view, fully ordered atomic arrangements in HCs are technically feasible but cumbersome. The growing condition of highly ordered HC requires elevated temperatures, which is an obstacle for efficient device implementation. Steady advances in thin film growth have led to improved conditions. Layer-by-layer growth has been demonstrated to reduce the crystallization energy of the materials, reducing the annealing temperatures to 225 °C, which avoids interfacial material intermixing (Dieny et al., 2020). A further reduction has been achieved when depositing HCs on a W seed layer. In this regard, the improvement in the growth conditions as well as the choice of appropriate substrates becomes essential to successfully incorporate Heusler alloy films into spintronic devices.

Two-dimensional (2D) van der Waals materials

A large variety of vdW materials are being investigated for spintronics, targeting different purposes even beyond the conventional applications described in the previous sections (Table 1). The materials that have attracted the most attention are (multilayer) graphene, transition metal dichalcogenides (TMDCs) (MX_2 with $\text{M} = \text{Mo}, \text{W}, \dots$ and $\text{X} = \text{S}, \text{Se}, \text{Te}$), hexagonal boron nitride (hBN), TIs of the Bi_2Te_3 family, and several magnetic materials, which belong to the most recent class of 2D materials discovered (Han et al., 2014; Soumyanarayanan et al., 2016; Avsar et al., 2020; Gibertini et al., 2019; Sierra et al., 2021; Yang et al., 2022; Wang et al., 2022).

Graphene and bilayer graphene present excellent spin transport properties, exhibiting very long spin diffusion length (up to $\sim 30 \mu\text{m}$), and are considered as a keystone for spin communications and, potentially, spin logic devices (Han et al., 2014; Avsar et al., 2020; Sierra et al., 2021). The spin-current propagation has been controlled using electric drift and thermal currents (Avsar et al., 2020; Sierra et al., 2021). However, the weak-SOI enabling slow spin relaxation in graphene prevents efficient spin manipulation and charge-to-spin interconversion. Control of spin flow in graphene by means of an electric gate was achieved with MoS_2 , which acted as a spin sink of variable strength. As the Schottky barrier between n -doped MoS_2 and graphene is suppressed with the gate, the MoS_2 shunts and absorbs the spin current, which can no longer propagate in graphene (Avsar et al., 2020; Vedmedenko et al., 2020; Sierra et al., 2021). A key element for these experiments is efficient spin injection into graphene. To circumvent the conductivity mismatch problem, resistive barriers are used (Avsar et al., 2020; Sierra et al., 2021), which are based on oxides such as AlO_x , MgO , TiO_x , YO_x and SrO or alternatives such hBN, fluorinated and hydrogenated graphene and amorphous carbon.

Table 1 Functionalities of representative van der Waals materials.

Electronic/Magnetic property	Representative vdW materials	Applications
Insulator	hBN	MTJ barrier, diffusion/intermixing barrier, encapsulation
Semiconductor	Black-Phosphorous, WS_2 , WSe_2 , MoSe_2 , MoS_2 , WSSe , SnS_2 , ReSe_2 , Bi_2Te_3 , etc	Spin transport (BP), SOT, optical spin injection, MTJ barrier, charge-spin conversion, SOI proximity
Semimetal	C, Si, Ge, WTe_2 , PtSe_2 , etc	MTJ barrier, spin-transport and diffusion/intermixing barrier, PMA (C), SOT, unconventional SOTs (e.g., 1 T'- WTe_2), charge-spin conversion
Metal	MoTe_2 , NbSe_2 , PdTe_2 , PtTe_2 , etc	SOT, charge-spin conversion
Ferromagnet	$\text{Fe}_{5-x}\text{GeTe}_2$ (metal), CrTe_2 (metal), $\text{Cr}_2\text{Ge}_2\text{Te}_6$ (semiconductor), MnSb_2Te_4 , CrCl_3 , CrBr_3 , etc	Spin injector, MTJ FM layers, magnetic proximity
Antiferromagnet	CrI_3 , CrCl_3 , MnPS_3 , FePS_3 , CrSBr (semiconductor), MnBi_2Te_4 , etc	TMR: insulating AFM (e.g., CrI_3) tunnel barrier, charge-spin conversion, magnetic proximity

Proximity SOI can be imprinted in graphene with large SOI materials such as some TMDC (Žutić et al., 2019). Spin relaxation anisotropy measurements in TMDC-graphene bilayers, using oblique spin precession, demonstrated a much larger spin lifetime for out-of-plane than for in-plane spins at room temperature (Sierra et al., 2021). The anisotropy, observed even when the Fermi level lies within the TMDC energy gap, is ascribed to valley Zeeman SOI and intervalley scattering induced in graphene by the TMDC (Garcia et al., 2018; Sierra et al., 2021). Subsequent experiments, using non-local spin Hall devices, further supported this conclusion. Room-temperature tuneable SHE, related to the valley Zeeman SOI, and ISGE, associated to induced Rashba SOI, were both observed in WS₂-graphene. The strength of the SOI deduced from the SHE measurements is in good agreement with the values extracted by density functional theory. Spin relaxation anisotropy has been also found in bilayer graphene and attributed to intrinsic spin-orbit splitting (Avsar et al., 2020; Vedmedenko et al., 2020). The SOI is small (about 24 μ V) but enough to induce an out-of-plane spin orbit field, which for high-quality devices reduces significantly the in-plane spin lifetime, as in the case of TMDC-graphene. The spin-relaxation anisotropy in bilayer graphene is strongly gate and temperature dependent, being maximum near the charge neutrality point and only observed at low temperatures (about 100 K).

Besides SOI, it is also possible to induce a magnetic-exchange field in graphene (Žutić et al., 2019; Vedmedenko et al., 2020; Sierra et al., 2021). Arguably, the most compelling evidence of proximity-induced exchange is reported in CrSBr-(bilayer) graphene heterostructures. CrSBr is a vdW semiconductor with a bandgap of about 1.5 eV and presents interlayer antiferromagnetic coupling with a Néel temperature of about 130 K. Within each layer, the material shows in-plane ferromagnetic order. When in contact to CrSBr, the bilayer graphene acquires a magnetization that is collinear to the magnetization of the closest CrSBr layer. By characterizing the nonlocal transport under an applied magnetic field, a large proximity exchange field of 170 T was estimated, which promoted an effective spin polarization in bilayer graphene of 14%. Additional evidence of magnetic proximity effects was found, for instance, in YIG-graphene, Cr₂Ge₂Te₆-graphene, CrBr₃-graphene, and CrSe-graphene structures.
